Preface

While we were preparing the seventh edition of the *Textbook of Diagnostic Microbiology*, a never-before-seen virus was reported in China in December 2019 and spread quickly around the world, reaching Europe and the United States in January 2020. This novel virus was identified as the severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), the cause of coronavirus disease 2019. This disease emphasizes how quickly infectious agents can spread and the significance of the work of microbiologists and other health care professionals. Newly recognized pathogens continue to emerge while previously known pathogens evolve to plague society.

The field of diagnostic microbiology continues to change dramatically and becomes more complex. Hence, we look ahead to the future needs of the next generation of medical laboratory practitioners. Methods for the detection and identification of infectious agents continue to evolve, and more laboratories are replacing traditional methods (e.g., biochemical identification of bacteria and cell cultures for viruses) with molecular biology assays. Therefore we continue to update and expand this topic in Chapter 11, where we discuss matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry and nucleic acid–based identification methods that include probes, amplification assays, and gene sequencing. This also includes nanomedicine in diagnosing infectious diseases. Bacteria continue to become more drug resistant, so science must keep pace by rapidly determining a bacterium’s susceptibility pattern and finding better ways to treat life-threatening infections. In Chapter 12, we discuss common means by which bacteria develop resistance to agents and present the most used and cutting-edge antimicrobial agents. We follow this in Chapter 13 by examining the best methods to assay for drug sensitivity and resistance.

With the advent of these emerging molecular technology innovations, scientific discoveries, and gene-based techniques, medical microbiology education in medical laboratory science programs has also undergone dramatic changes. In these highly specialized and rapidly advancing areas of science and biotechnology, we have taken the lead to constantly look for innovative ways to effectively deliver the textbook contents in ways that they are current, appropriate, absorbable, and applicable.

As in previous editions, the seventh edition maintains the characteristic features of a well-designed and organized textbook. We maintain the building-block approach to learning, critical thinking, and problem solving, attributes that students of medical laboratory science and medical laboratory technology, entry-level clinical laboratory scientists, and others have found valuable and effective. The primary goal of the *Textbook of Diagnostic Microbiology* is to provide a strong foundation for medical laboratory science students, entry-level practitioners, and other health care professionals; therefore discussions on organisms are limited to those that are medically

important and commonly encountered, as well as new and re-emerging pathogens. A feature that sets our textbook apart is the large number of quality full-color photographs and photomicrographs. The text also provides students and other readers with valuable learning tools, such as summary tables, flowcharts, and descriptive illustrations, to help them comprehend the vast amount of information and reinforce learning. In response to our readers’ needs, we continued our efforts to enhance these features that have made this textbook user-friendly. All our contributing authors are experts in the field of microbiology, either practicing laboratory scientists, infectious disease specialists, researchers, or educators. Their expertise helps us to have current and accurate information.

Organization

Part I remains the backbone of the textbook, providing important background information; Part II focuses on laboratory identification of etiologic agents organized taxonomically; and Part III on the *organ system approach*—the clinical and laboratory diagnoses of infectious diseases at various body sites.

Part 1 presents basic principles and concepts of diagnostic microbiology, including quality assurance, providing students with a firm theoretic foundation. Chapters 7 (Microscopic Examination of Materials From Infected Sites) and 8 (Use of Colony Morphology for the Presumptive Identification of Microorganisms) still play a vital role in this text. These two chapters help students and practitioners who may have difficulty recognizing bacterial morphology on direct smear preparations and colony morphology on primary culture plates develop these skills with the use of color photomicrographs of stained direct smears and cultures from clinical samples. These two chapters also illustrate how microscopic and colony morphology of organisms can aid in the initial identification of the bacterial isolate. Chapter 9 introduces the student/reader to the principles behind various biochemical methods for identification of gram-negative bacteria. This chapter contains several color photographs to help our readers understand the principles and visualize interpretations of these important tests.

Part 2 highlights methods for the identification of clinically significant isolates that include bacteria, fungi, parasites, and viruses. Although diseases caused by the infectious agents are discussed, the emphasis is on the characteristics and methods used to isolate and identify each group of pathogens. Numerous tables summarize the major features of organisms and use schematic diagrams to show the relationships and differences among similar or closely related species. Chapters devoted to anaerobic bacterial species, medically important fungi, parasites, and viruses affirm the

significance of these agents. Chapter 29 includes a discussion on viral pathogens, including newly discovered Zika virus, SARS-CoV-2, and avian influenza virus. Chapter 31 describes biofilm—an increasingly complex entity. It has become evident that microbial biofilms are involved in the pathogenesis of several human diseases and may be a contributing factor of antimicrobial therapy failure.

The organ system approach in Part 3 has been the foundation of the *Textbook of Diagnostic Microbiology* and provides an opportunity for students and other readers to “pull things together.” The chapters in Part 3 begin with the anatomic considerations of the organ system to be discussed and the role of the usual microbiota found at a particular site in the pathogenesis of a disease. It is important for students to be knowledgeable about the usual inhabitants at a body site before they can appreciate the significance of the infectious agents they are most likely to encounter. These chapters also discuss proper specimen collection and processing.

Pedagogic features

As in previous editions, the “Case in Point” case study found in all chapters introduces the reader to an important pathogen, infectious disease, concept, or principle that is discussed in the chapter text and is used to lead the learner to the main context discussed in the chapter. The Case in Point is followed by “Issues to Consider.” These points are presented in a bulleted format, and learners are asked to think about them as they read the chapter. We use case studies to enhance problem-solving and critical-thinking skills. The case studies describe clinical and laboratory findings, providing students with opportunities to correlate these observations with possible etiologic agents. In most cases, the cause of the illness is not disclosed in the case study; rather, it is presented elsewhere in the chapter to give students the opportunity to independently determine the explanations. In Part 3, the case studies also help students apply the knowledge they acquired from Parts 1 and 2.

“Case Check” boxes aim to reinforce understanding of the content or concept within the context of the Case in Point at the beginning of the chapter or case study at the beginning of a section within the chapter. The Case Check highlights a

specific point in the text and intends to help the learner connect the dots between the points under discussion, as illustrated by the case study.

To further reinforce learning, identification tables, flowcharts, and featured illustrations have been updated, and new ones have been added. Learning objectives and a list of key terms are also provided at the beginning of each chapter. The list of key terms includes abbreviations used in the text so that students can easily find them. At the end of each chapter, readers will find “Points to Remember” and “Learning Assessment Questions,” which help reinforce comprehension and understanding of important concepts. Points to Remember includes a bulleted list of important concepts and highlights that the reader should have learned from the chapter. We also include answers to all the learning assessment questions found in each chapter.

Ancillaries for instructors and students

As in the case of previous editions, we continue to offer a variety of instructor ancillaries specifically geared for this book. For instructors, the Evolve website includes a test bank containing more than 1200 questions. It also includes an electronic image collection and PowerPoint slides. For students, the Evolve website will include a laboratory manual like it always has, which contains new case studies and student review questions. It also includes appendices, which provide information on laboratory media commonly used for the cultivation of bacteria and fungi as well as detailed protocols for selected clinical microbiology laboratory tests.

Acknowledgments

We are grateful to all contributing authors, students, instructors, and many other individuals, who have all made invaluable suggestions and comments on ways to improve this edition.

PART

1

Introduction to clinical microbiology

Bacterial cell structure, physiology, metabolism, and genetics

Connie R. Mahon

CHAPTER OUTLINE

Overview of the microbial world, 4

- Bacteria, 4
- Parasites, 4
- Fungi, 4
- Viruses, 6

Classification/Taxonomy, 6

- Nomenclature, 6
- Classification by phenotypic and genotypic characteristics, 7
- Classification by cellular type: prokaryotes, eukaryotes, and archaea, 7

Comparison of prokaryotic and eukaryotic cell structure, 7

- Prokaryotic cell structure, 7
- Eukaryotic cell structure, 10
- Cytoplasmic structures, 7

Bacterial morphology, 11

- Microscopic shapes, 11
- Common stains used for microscopic visualization, 11

Microbial growth and nutrition, 13

- Nutritional requirements for growth, 14
- Environmental factors influencing growth, 15
- Bacterial growth, 15

Bacterial biochemistry and metabolism, 16

- Metabolism, 16
- Fermentation and respiration, 16
- Biochemical pathways from glucose to pyruvic acid, 17
- Anaerobic utilization of pyruvic acid (Fermentation), 17
- Aerobic utilization of pyruvate (Oxidation), 18
- Carbohydrate utilization and lactose fermentation, 19

Microbial genetics, 19

- Anatomy of a DNA and RNA molecule, 19
- Terminology, 21
- Genetic elements and alterations, 21
- Mechanisms of gene transfer, 22

Bibliography, 24

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Differentiate among archaeal, prokaryotic (bacterial), and eukaryotic cell types.
2. Describe microbial classification (taxonomy).
3. Accurately apply the rules of scientific nomenclature for bacterial names.
4. List and define five methods used by epidemiologists to subdivide bacterial species.
5. Contrast prokaryotic and eukaryotic cytoplasmic and cell wall structures and functions.
6. Compare the cell walls of gram-positive and gram-negative bacteria.
7. Explain why acid-fast bacteria do not stain well with the Gram stain.
8. Justify the use of the following stains in the diagnostic microbiology laboratory: Gram stain, acid-fast stains (Ziehl-Neelsen, Kinyoun, auramine-rhodamine), acridine orange, methylene blue, calcofluor white, lactophenol cotton blue, and India ink.
9. Describe the nutritional requirements for bacterial growth, and define the categories of media used for culturing bacteria in the laboratory.
10. Define the atmospheric requirements of obligate aerobes, microaerophiles, facultative anaerobes, obligate anaerobes, aerotolerant anaerobes, and capnophilic bacteria.
11. Differentiate an aerotolerant anaerobe from facultative and obligate anaerobes.
12. Describe the stages in the growth (i.e., growth curve) of bacterial cells.
13. Explain the importance of understanding microbial metabolism in clinical microbiology.
14. Differentiate between fermentation and oxidation (aerobic respiration).
15. Compare the three biochemical pathways that bacteria use to convert glucose to pyruvate.
16. Differentiate the two types of glucose fermentation that explain positive results with the methyl red and Voges-Proskauer tests.
17. Define the following genetic terms: *genotype*, *phenotype*, *constitutive*, *inducible*, *replication*, *transcription*, *translation*, *genome*, *chromosome*, *plasmids*, *insertion sequence element*, *transposon*, *point mutations*, *frameshift mutations*, *missense mutations*, *nonsense mutations*, and *recombination*.
18. Discuss the development and transfer of antimicrobial resistance in bacteria.

19. Differentiate among the mechanisms of transformation, transduction, and conjugation in the transfer of genetic material from one bacterium to another.
20. Define the terms *bacteriophage*, *lytic phage*, *lysogeny*, and *temperate phage*.
21. Define the term *restriction endonuclease enzyme* and explain how it applies to the clinical microbiology laboratory.

KEY TERMS

Acid fast	Microaerophilic
Aerobic respiration (oxidation)	Minimal medium
Aerotolerant anaerobes	Mycelia
Anticodon	Nomenclature
Archaea	Nutrient media
Autotroph	Obligate aerobes
Bacteria	Obligate anaerobes
Bacteriophage	Pathogenic bacteria
Capnophilic	Phenotype
Capsule	Phyla
Codon	Pili
Competent	Plasmids
Conjugation	Pleomorphic
Differential media	Prokaryote
Dimorphic	Protein expression
Eukarya	Psychrophile
Eukaryote	Replication
Facultative anaerobes	Restriction enzymes
Family	Selective media
Fermentation	Species
Fimbriae	Spore
Flagella	Strains
Fusiform	Taxa
Genotype	Taxonomy
Genus	Temperate
gram-negative	Thermophile
gram-positive	Transcription
Halophile	Transduction
Heterotroph	Transformation
Hyphae	Translation
Krebs cycle	Transport medium
Lysogeny	Virion
Mesophiles	

Case in point

A 4-year-old female patient presents with symptoms of redness, burning, and light sensitivity in both eyes. She also complains of her eyelids sticking together because of exudative discharge. A Gram stain of the conjunctival exudates (product of acute inflammation with white blood cells and fluid) shows gram-positive intracellular and extracellular, faint-staining, coccobacillary bacteria. The organisms appear to have small, clear, nonstaining “halos” surrounding each cell. This clear area is noted to be between the stained organism and the amorphous (no definite form; shapeless) background material. The Gram stain of the quality control organisms *Staphylococcus aureus* (gram-positive) and *Escherichia coli* (gram-negative) reveals gram-positive reactions for both organisms.

Issues to consider

After reading the patient's case history, consider:

- Role of microscopic morphology in presumptive identification
- Significance of observable cellular structures
- Importance of quality control in assessing and interpreting direct smear results
- Unique characteristics of organisms, such as cellular structures, in initiating infection and disease in hosts

Microbial inhabitants have evolved to survive in various ecologic niches (place or location) and habitats (organism's location and where its resources may be found). Some grow rapidly, and others grow slowly. Some can replicate with a minimal number of nutrients present, whereas others require complex, enriched nutrients to survive. Variation exists in atmospheric growth conditions and temperature requirements. This diversity exists in microorganisms that inhabit the human body as normal biota (flora), as opportunistic pathogens, or as true pathogens. Each microbe has its own physiology and metabolic pathways that allow it to survive in its particular habitat. A main role of the clinical microbiologist is to isolate, identify, and analyze the bacteria that cause disease in humans (pathogens). Recent advances in molecular biology methods, such as nucleic acid amplification, nucleic acid sequencing, and matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry, have shifted identification away from traditional biochemical testing for identification of bacterial isolates. Nevertheless, knowledge of microbial structure and physiology is extremely important to clinical microbiologists in the following areas:

- Microscopic characterization of organisms
- Recovery of organisms in culture from patient specimens
- Characterization and identification of organisms after they have been isolated
- Interpretation of antimicrobial susceptibility patterns

The first step in bacterial identification is often microscopic characterization—describing the shape of the organism and its staining characteristics, which are based on the cell wall structure. Understanding the growth requirements of a particular bacterium enables the microbiologist to select the appropriate medium for primary culture and optimize the recovery and isolation of the pathogen. This is followed by observation of the metabolic biochemical differences among organisms that form the basis for many bacterial identification systems in use today. The cell structure and biochemical pathways of an organism also determine its susceptibility to various antimicrobial agents. The ability of microorganisms to change rapidly, acquire new genes, and undergo mutations presents continual challenges to clinical microbiologists as they isolate and characterize microorganisms associated with infectious diseases in humans.

This chapter provides a review of the structure, physiology, metabolism, and genetics of prokaryotic and eukaryotic cells. It also gives examples of common stains used to microscopically visualize microorganisms. Each topic in this chapter emphasizes to clinical microbiologists the inherent importance of their efforts to culture, identify, and characterize the microbes that cause disease in humans.

Overview of the microbial world

The study of microorganisms by the Dutch biologist and lens maker Anton van Leeuwenhoek has evolved immensely from its early historic beginnings. Because of Leeuwenhoek's discovery of what he affectionately called *wee beasties* and *animalcules* in a water droplet with his home-made microscope, the scientific community acknowledged him as the "father of protozoology and bacteriology." Today, we know that there are enormous numbers of microbes in, on, and around us in our environment. The vast majority of these microbes do not cause disease. This textbook focuses on microbes that are associated with human disease.

Bacteria

Bacteria are unicellular organisms that are classified as **prokaryotes** (Greek: before kernel [nucleus]). They lack a nuclear membrane and a true nucleus, mitochondria, an endoplasmic reticulum (ER), and Golgi bodies. The absence of the preceding bacterial cell structures differentiates them from **eukaryotes** (Greek *eu*: well or good; Greek *karyon*: kernel). [Table 1.1](#) compares prokaryotic and eukaryotic cell organization; [Fig. 1.1](#) shows both types of cells.

Parasites

Certain eukaryotic parasites (organisms that live at the expense of their hosts) exist as unicellular organisms of microscopic size, whereas others are multicellular organisms. Protozoa are unicellular organisms within the kingdom Protista that obtain their nutrition through ingestion. Some are capable of locomotion (motile), whereas others are non-motile. They are categorized by their locomotive structures: flagella (Latin: whiplike), pseudopodia (Greek: false feet), or cilia (Latin: eyelash). Many multicellular parasites can be quite large; for example, tapeworms may be 7 to 10m long (see [Chapter 28](#)).

Fungi

Fungi are heterotrophic (cannot produce all of its nutrients) eukaryotes that obtain nutrients through absorption. Most fungi are multicellular, and many can reproduce sexually and asexually. Multicellular fungi are composed of filaments called **hyphae** that interweave to form mats called **mycelia**. Yeasts are unicellular fungi that reproduce asexually. "True" yeasts do not form hyphae or mycelia. Molds are filamentous forms that can reproduce asexually and sexually. Certain fungi can assume both morphologies (yeast and hyphae/mycelial

Table 1.1 Comparison of prokaryotic and eukaryotic cell organization

Characteristic	Prokaryote	Eukaryote
Typical size	0.4–2 μ m in diameter 0.5–5 μ m in length	10–100 μ m in diameter >10 μ m in length
Nucleus	No nuclear membrane; nucleoid region of the cytosol	Membrane-bound nucleus
Genome		
Location	In the nucleoid, at the mesosome	In the nucleus
Chromosomal DNA	Circular; complexed with RNA	Linear; complexed with basic histones and other proteins
Extrachromosomal circular DNA	Plasmids, small circular molecule of DNA in the cytoplasm containing accessory information; most commonly found in gram-negative bacteria; each carries genes for its own replication; can confer resistance to antimicrobial agents	In mitochondria, chloroplasts, and cytoplasm
Reproduction	Asexual (binary fission)	Sexual and asexual
Membrane-bound organelles	Absent	All
Golgi bodies	Absent in all	Present in some
Lysosomes	Absent in all	Present in some; contain hydrolytic enzymes
Endoplasmic reticulum	Absent in all	Present in all; lipid synthesis, transport
Mitochondria	Absent in all	Present in most
Chloroplasts for photosynthesis	Absent in all	Present in algae and plants
Ribosomes: site of protein synthesis (nonmembranous)	Present in all	Present in all
Size	70S consisting of 50S and 30S subunits	80S consisting of 60S and 40S subunits
Electron transport for energy	In the cell membrane; no mitochondria present	In the inner membrane of mitochondria and chloroplasts

Table 1.1 Comparison of prokaryotic and eukaryotic cell organization—cont'd

Characteristic	Prokaryote	Eukaryote
Sterols in cytoplasmic membrane	Absent except in Mycoplasmataceae	Present
Plasma membrane	Phospholipid bilayer; lacks carbohydrates	Phospholipid bilayer; also contains glycolipids and glycoproteins
Cell wall, if present	Peptidoglycan in most bacteria	Cellulose, phenolic polymers, lignin (plants), chitin (fungi), other glycans (algae)
Glycocalyx	Present in many as an organized capsule or unorganized slime layer	Present; some animal cells
Cilia	Absent	Present; see description of flagella
Flagella, if present	Simple flagella; composed of polymers of flagellin; movement by rotary action at the base; spirochetes have MTs	Complex cilia or flagella; composed of MTs and polymers of tubulin with dynein connecting MTs; movement by coordinated sliding MTs
Pili and fimbriae	Present	Absent

MT, Microtubule.

Fig. 1.1 Comparison of prokaryotic and eukaryotic cell organization and structures. A, Prokaryotic gram-positive and gram-negative bacteria. B, Structure of the generalized eukaryotic cell. (A, From Murray, P. R., et al. (2009). *Medical microbiology* [6th ed]. Philadelphia: Mosby; B, from Thibodeau, G. A., & Patton, K. T. (2007). *Anatomy and physiology* [6th ed]. St Louis: Mosby.)

forms), growing as yeast at human temperature (37° C) and as the filamentous form at room temperature (22° C). These fungi are called **dimorphic**. Some systemic fungal diseases in human hosts are caused by dimorphic fungi (see [Chapter 27](#)).

Viruses

Viruses are the smallest infectious particles and cannot be seen under an ordinary light microscope. Often, we can see their effects on cell lines grown in the laboratory, such as inclusions, rounding up of cells, and syncytium (fusion of host cells into multinucleated infected forms), where these characteristics become diagnostic for many viral diseases. These visible changes are called *cytopathic effect*. Viruses are acellular (not composed of cells) and are therefore neither prokaryotic nor eukaryotic. They are distinguished from living cells by the following characteristics:

- Viruses consist of deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), but rarely both. Their genome can be double-stranded DNA (dsDNA), single-stranded DNA (ssDNA), double-stranded RNA (dsRNA), or single-stranded RNA (ssRNA).
- Viruses lack cytoplasmic membranes and are surrounded by a protein coat.
- Viruses are obligate intracellular parasites that cannot self-replicate. They require host cells for replication (increase in number does not involve mitosis, meiosis, or binary fission) and metabolism. Because they lack ribosomes and other metabolites, they “take over” host cell function using the host cell machinery to reproduce. Growth (increase in size) does not occur in viruses.

Viruses are mostly host or host cell specific. For example, human immunodeficiency virus infects T-helper lymphocytes, not muscle cells, in humans, whereas other viruses, such as the rabies virus, can infect dogs, skunks, bats, humans, and other animals. A virus that infects and possibly destroys bacterial cells is known as a **bacteriophage** (Greek *phage*: to eat). Viruses are classified and identified by their genome (DNA or RNA), host range, host disease signs and symptoms, chemical makeup, geographic distribution, the presence or absence of an envelope, their resistance to changes in pH and temperature, their antigenicity (serologic methods), how the virus replicates, and the **virion** (a complete virus outside a cell) size (see [Chapter 29](#)).

Classification/Taxonomy

Taxonomy (Greek *taxes*: arrangement; Greek *nomos*: law) is the orderly classification and grouping of organisms into **taxa** (categories). Taxonomy involves three structured, interrelated categories: classification/taxonomy, nomenclature, and identification. It is based on similarities and differences in **genotype** (genetic makeup of an organism, or combinations of forms of one or a few genes in an organism’s genome) and **phenotype** (observable physical and functional features of an organism expressed by its genotype). Examples of genotypic characteristics include base sequencing of DNA or RNA and DNA base composition ratio to measure the degree of relatedness

of two organisms (see later in this chapter and [Chapter 11](#)). Examples of microbial phenotypic characteristics include macroscopic (colony morphology on media) and microscopic morphology (size, shape, arrangement into groups or chains of cells), staining characteristics (gram-positive or gram-negative), nutritional requirements, physiologic and biochemical characteristics, antigenic markers, and susceptibility or resistance to antimicrobial agents or chemicals. See [Chapters 7, 8, 9, 12, and 13](#) for more detailed information.

Taxa (plural of *taxon*), for example, the levels of classification, are the categories or subsets in taxonomy. The formal levels of bacterial classification in successively smaller taxa or subsets are domain, kingdom, division (or phylum in kingdom Animalia), class, order, family, tribe, genus, species, and subspecies. Below the subspecies level, designations such as serotype or biotype may be given to organisms that share specific minor characteristics. Protists (protozoans) of clinical importance are named similarly to animals; instead of divisions, **phyla** (plural of *phylum*) is used, but the names of the other classifications remain the same. Prokaryotes are placed in the domains Bacteria and **Archaea** (Greek: ancient, origin from the earliest cells), separate from the animals; plants and protists are placed in the domain **Eukarya**. The domains Bacteria and Archaea include unicellular prokaryotic organisms.

Clinical microbiologists traditionally emphasize placement and naming of bacterial species into three (occasionally four or five) categories: the **family** (similar to a human “clan”), a **genus** (equivalent to a human last name), and a **species** (equivalent to a human first name). The plural of genus is *genera*. For example, there are many genera in the family Staphylococcaceae. The proper word for the name of a species is an *epithet*. For example, *Staphylococcus* (genus) *aureus* (species epithet) belongs to the family Staphylococcaceae. Although order and tribe may be useful for the classification of plants and animals, these taxa are not always used for the classification of bacteria. In addition, there are usually different **strains** within a given species of the same species. As an example, there are many different strains of *S. aureus*. If the *S. aureus* isolated from one patient is resistant to penicillin and another *S. aureus* isolate from a different patient is susceptible to penicillin, the two isolates belong to different strains of the same species.

Nomenclature

Nomenclature provides naming assignments for each organism. The following standard rules for denoting bacterial names are used. The family name is capitalized and has an “-aceae” ending (e.g., Micrococcaceae). The genus name is capitalized and followed by the species epithet, which begins with a lowercase letter; both the genus and species should be italicized in print but underlined when written in script (e.g., *Staphylococcus aureus* or Staphylococcus aureus). Often the genus name is abbreviated by use of the first letter (capitalized) of the genus followed by a period and the species epithet (e.g., *S. aureus*). The genus name followed by the word *species* (e.g., *Staphylococcus species*) may be used to refer to the genus as a whole. Species are abbreviated “sp.” (singular) or “spp.” (plural) when the species is not specified. When bacteria are referred to as a group, their names are neither capitalized nor underlined (e.g., staphylococci).

Classification by phenotypic and genotypic characteristics

The traditional method of placing an organism into a particular genus and species is based on the similarity of all members in numerous phenotypic characteristics. In the diagnostic microbiology laboratory, this classification is accomplished by testing each bacterial culture for various metabolic or molecular characteristics and comparing the results with those listed in established tables or databases. In many rapid identification systems, a numeric taxonomy is used in which phenotypic characteristics are assigned a numeric value, and the derived number indicates the genus and species of the bacterium by consulting a database of known organisms.

Epidemiologists constantly seek means of further subdividing bacterial species to follow the spread of bacterial infections. Species are subdivided into subspecies (abbreviated “subsp.”) on the basis of phenotypic differences, serovarieties (abbreviated “serovar”) on the basis of serologic (antigenic) differences, or biovarieties (abbreviated “biovar”) on the basis of biochemical test result differences. Phage typing (based on susceptibility to specific bacterial phages) is also used for this purpose. Current technology allows the analysis of genetic relatedness (DNA and RNA structure and homology) for taxonomic purposes. The analysis of ribosomal RNA (rRNA) gene sequencing is particularly useful for this purpose. The information obtained from these studies resulted in the reclassification of some bacteria.

Classification by cellular type: prokaryotes, eukaryotes, and archaea

Based on cell organization and function, organisms fall into one of three distinct groups: prokaryotes, eukaryotes, or archaea. Taxonomists placed all organisms into three domains that replaced some kingdoms: Bacteria, Archaea, and Eukarya. These three domains are the largest and most inclusive taxa. Each domain is divided into kingdoms on the basis of the similarities of RNA, DNA, and protein sequences. The group prokaryotes includes the domains Archaea and Bacteria (Eubacteria), whereas fungi, algae, protozoa, animals, and plants are eukaryotic in nature and are placed in the domain Eukarya.

The domain Archaea (formerly Archaeobacteria) cell type appears to be more closely related to eukaryotic cells than to prokaryotic cells and is found in microorganisms that grow under extreme environmental conditions. Archaeal cell walls lack peptidoglycan, a major reason they are placed in a domain separate from bacteria. These microbes share some common characteristics with bacteria; they too can stain gram-positive or gram-negative. Gram-positive archaea have a thick wall and stain purple. Gram-negative archaeal cells, in contrast with the typical gram-negative bacterial lipid membrane, have a layer of protein covering the cell wall and stain pink. See the “Gram Stain” section later in this chapter.

The structure of the cell envelope and enzymes of archaea allows them to survive under stressful or extreme (*extremophiles*; lovers of the extreme) conditions. Examples include

halophiles (salt-loving cells) in Utah’s Great Salt Lake, **thermophiles** (heat-loving cells) in hot springs and deep ocean vents, and the anaerobic methanogens that release swamp gas and inhabit the intestinal tracts of animals. Because archaea are not encountered in clinical microbiology, they are not discussed further in this textbook.

In general, the interior organization of eukaryotic cells is more complex than that of prokaryotic cells (see Fig. 1.1). The eukaryotic cell is usually larger and contains membrane-encased organelles (“little organs”) or compartments that serve specific functions, whereas the prokaryotic cell is non-compartmentalized. Various structures are unique to prokaryotic cells (see Fig. 1.1). Differences also exist in the processes of DNA synthesis, protein synthesis, and cell wall synthesis and structure. Table 1.1 compares the major characteristics of eukaryotic and prokaryotic cells.

Pathogenic (disease-causing) **bacteria** are prokaryotic cells that infect eukaryotic hosts. Antimicrobial agents targeting unique prokaryotic structures and metabolism inhibit bacterial growth without harming eukaryotic host cells. This is one reason that pharmaceutical companies have been successful in developing effective antimicrobial agents against bacterial pathogens. However, finding drugs effective against parasites and fungi, which are eukaryotic and resemble their human hosts, and viruses, which use host cells for replication, is less successful. In addition, as a result of genetic changes, bacteria continue to acquire drug resistance.

Comparison of prokaryotic and eukaryotic cell structure

Prokaryotic cell structure

Cytoplasmic structures

Bacteria do not contain a membrane-bound nucleus. Their genome consists of a single circular chromosome. This appears as a diffuse nucleoid or chromatin body (nuclear body) that is attached to a mesosome, a saclike structure in the cell membrane.

Bacterial ribosomes, consisting of RNA and protein, are found free in the cytoplasm and attached to the cytoplasmic membrane. They are the site of protein synthesis. They are 70S in size and dissociate into two subunits: 50S and 30S (see Table 1.1). The *S* stands for *Svedberg units*, which refer to sedimentation rates (unit of time) during high-speed centrifugation. The Svedberg unit is named for Theodor Svedberg, Nobel Prize winner and inventor of the ultracentrifuge. Larger particles have higher *S* values. The *S* value is *not additive*. When the previously mentioned two subunits 50S and 30S bind together, there is a loss of surface area, and the two subunits produce a complex 70S in size. The same occurs in the eukaryotic cell, where the two subunits 60S and 40S combine to form an 80S complex.

Stained bacteria sometimes reveal the presence of cytoplasmic granules. These granules are storage deposits and may consist of polysaccharides such as glycogen, lipids such as poly β -hydroxybutyrate, or polyphosphates. These granules are sometimes referred to as *metachromatic granules* and can be visualized with the methylene blue stain.

Certain genera, such as *Bacillus* and *Clostridium*, produce endospores in response to harsh environmental conditions. Endospores are small, dormant (inactive), asexual spores that develop inside the bacterial cell as a means of survival, not reproduction. Their thick protein coat makes them highly resistant to chemical agents, temperature change, starvation, dehydration, ultraviolet and gamma radiation, and desiccation. Under harsh conditions, each vegetative cell (active, capable of growing and dividing) produces one endospore (inactive) that later germinates under favorable environmental conditions into one vegetative cell. Endospores should not be confused with the reproductive spores of fungi (see Chapter 27).

Spores appear as highly refractile bodies in the cell and are visualized with Gram stain as unstained areas in a cell because of their thick protein coat. With the *Schaeffer-Fulton* stain, the most commonly used endospore stain, endospores appear green (malachite green is used as the primary stain), and the bacterial cells are red (safranin is the counterstain). The size, shape, and interior location of the spore, for example, at one end (terminal), subterminal, or central, can be used as identifying characteristics. For instance, the terminal spore of *Clostridium tetani*, the etiologic (causative) agent of tetanus, causes swelling of the thin rod-shaped cell giving the organism a characteristic tennis racquet-shaped or lollipop-shaped appearance.

Cell envelope structures

The cell envelope consists of the membrane and structures surrounding the cytoplasm. In bacteria, these are the plasma membrane and the cell wall. Some species also produce capsules and slime layers.

Plasma (Cell) membrane

The plasma membrane is a phospholipid bilayer with embedded proteins that surrounds the cytoplasm. The prokaryotic plasma membrane is made of phospholipids and proteins and (except for those in the family *Mycoplasmataceae*, which

do contain sterols) does not contain sterols. This is in contrast with eukaryotic plasma membranes, which contain sterols. The plasma membrane acts as an osmotic barrier (prokaryotes have a high osmotic pressure inside the cell) and is the location of the electron transport chain, where energy is generated. The general functions of the prokaryotic plasma membrane are identical to functions in eukaryotes, except for energy generation (Fig. 1.2).

Cell wall

The cell wall of prokaryotes is a rigid structure that maintains the shape of the cell and prevents bursting of the cell from the high osmotic pressure inside it. Cell walls in bacteria have been traditionally categorized according to their staining characteristics. The two major types of cell walls are **gram-positive** and **gram-negative** (see Fig. 1.1A). They can be differentiated by the Gram stain.

Gram-positive cell wall

The gram-positive cell wall is composed of a very thick peptidoglycan (murein) layer. The peptidoglycan layer consists of glycan (a polysaccharide) and chains of alternating *N*-acetyl-D-glucosamine (NAG) and *N*-acetyl-D-muramic acid (NAM) (Fig. 1.3). Short peptides, each consisting of four amino acid residues, are attached to a carboxyl group on each NAM residue. The chains are then cross-linked to form a thick network via a peptide bridge (differing in number of peptides) connected to the tetrapeptides on the NAM. Because the peptidoglycan layer is the principal component of the gram-positive cell wall, antimicrobial agents that target gram-positive organisms (e.g., penicillins) are effective by preventing synthesis of peptidoglycan. Gram-negative bacteria, which have a different cell wall structure, are less affected by these agents.

Other components of the gram-positive cell wall that penetrate to the exterior of the cell are teichoic acid, anchored to the peptidoglycan, and lipoteichoic acid, anchored to the plasma membrane. These two components are unique to the gram-positive cell wall. Other antigenic polysaccharides may be present on the surface of the peptidoglycan layer.

Fig. 1.2 Structure of the plasma membrane. (From Thibodeau, G. A., & Patton, K. T. (2007). *Anatomy and physiology* [6th ed]. St Louis: Mosby.)

Fig. 1.3 The structure of the peptidoglycan layer in the cell wall of *Escherichia coli*. The amino acids in the cross-linking tetrapeptides may differ among species. NAG, N-acetyl-D-glucosamine; NAM, N-acetyl-D-muramic acid. (From Neidhardt, F. C., et al. (1990). *Physiology of the bacterial cell: a molecular approach*. Sunderland, MA: Sinauer Associates.)

Gram-negative cell wall

The cell wall of gram-negative bacteria comprises two layers: the inner peptidoglycan layer, which is much thinner than in gram-positive cell walls, and an additional outer membrane unique to the gram-negative cell wall. The outer membrane, sometimes called an *envelope*, contains proteins, phospholipids, and lipopolysaccharide (LPS). LPS contains three regions: an antigenic O-specific polysaccharide, a core polysaccharide, and an inner lipid A (also called *endotoxin*). The lipid A moiety is responsible for producing fever and shock in animals infected with gram-negative bacteria. The toxicity varies among different bacterial species. The outer membrane has the following functions:

- It acts as a barrier to hydrophobic compounds and harmful substances.
- It acts as a sieve, allowing water-soluble molecules to enter through protein-lined channels called *porins*.
- It provides attachment sites that enhance attachment to host cells.

Between the outer membrane and the inner membrane and encompassing the thin peptidoglycan layer is an area referred to as the *periplasmic space*. Within the periplasmic space is a gel-like matrix containing nutrient-binding proteins and degradative and detoxifying enzymes. The periplasmic space is absent in gram-positive bacteria.

Acid-fast cell wall

Certain genera, such as *Mycobacterium* and *Nocardia*, have a gram-positive cell wall structure and are classified as gram-positive bacteria. However, because they contain a waxy layer of glycolipids and fatty acids (mycolic acid) bound to the exterior of the cell wall, they stain poorly with the Gram stain. More than 60% of the cell wall is lipid, and the major lipid component is mycolic acid, a strong hydrophobic molecule that forms a lipid shell around the organism and affects its permeability. This excludes water-soluble

Case check 1.1

The differential ability of the Gram stain makes it useful in classifying a bacterium as gram-positive or gram-negative. As in the Case in Point, correct interpretation and assessment of the Gram-stained smear results are critical in the presumptive identification of the organism present. See also Procedure 12 in [Appendix D on Evolve](#). The use of quality control organisms with known Gram stain reactions ensures that the Gram stain procedure is performed correctly. Bacteria with a thick peptidoglycan layer in the cell wall containing teichoic acid cross-linkages retain the crystal violet-iodine dye complex after decolorization and appear deep blue. They are gram-positive (e.g., *S. aureus*). Bacteria that possess an outer membrane, a lipid bilayer, and a thin layer of peptidoglycan do not retain the dye complex when exposed to a decolorizer. They are gram-negative (e.g., *E. coli*). The alcohol-acetone decolorizer damages the outer membrane of gram-negative bacteria and allows the stain complex to wash out. All unstained elements, such as gram-negative bacteria and products of inflammation, are subsequently counterstained red by the dye safranin. Older, dying, or dead gram-positive bacterial cells, having lost the integrity of the thick peptidoglycan layer, are not able to retain the crystal violet-iodine complex and will also appear red.

dyes and makes *Mycobacterium* spp. difficult to stain with the Gram stain. Mycobacteria are best seen with an acid-fast stain, in which carbol fuchsin is the primary stain, followed by an acid-alcohol decolorizer. See "Acid-fast Stains" later in this chapter and also Procedure 12 in Appendix D on Evolve.

Absence of cell wall

Prokaryotes that belong to the genera *Acholeplasma*, *Mycoplasma*, and *Ureaplasma* are unique in that they lack a cell wall and contain sterols in their plasma membranes. Because they lack the rigidity of the cell wall, they are seen in various shapes microscopically referred to as being **pleomorphic**. Some gram-positive and gram-negative cells can lose their cell walls and grow as L-forms in media supplemented with serum or sugar to prevent osmotic rupture of the cell membrane.

Surface polymers

Various pathogenic bacteria produce a discrete organized covering termed a **capsule**. Capsules are usually made of polysaccharide polymers, although they may also be made of polypeptides. Capsules act as virulence factors in helping the pathogen evade phagocytosis. During identification of certain bacteria by serologic typing, capsules sometimes must be removed to detect the somatic (cell wall) antigens present underneath them. Capsule removal is accomplished by boiling a suspension of the microorganism. *Salmonella* Typhi must have its capsular (Vi) antigen removed for the laboratory scientist to observe agglutination with *Salmonella* somatic (O) antisera. The capsule does not ordinarily stain with use of common laboratory stains, such as Gram stain or India ink. Instead, it appears as a clear area (“halo like”) between or surrounding the stained organism and the stained amorphous background material in a direct smear from a clinical specimen.

Slime layers or a *glycocalyx* are similar to capsules but are more diffuse layers surrounding the cell. They also are made of polysaccharides and serve either to inhibit phagocytosis or, in some cases, to aid in adherence to host tissue or synthetic implants. Glycocalyx production can be the first step in the formation of a biofilm (see [Chapter 31](#)).

Case check 1.2

The most common mechanism for evading phagocytosis used by many microorganisms is having a surface polysaccharide capsule. Microorganisms possessing a capsule are generally highly virulent, as in the Case in Point, until removal of the capsule, at which point virulence becomes extremely low. Encapsulated strains of *Streptococcus pneumoniae* and *Haemophilus influenzae* are associated with highly invasive infections and are known to be more virulent than nonencapsulated strains. See also the discussion on the ability to resist phagocytosis in [Chapter 2](#). Antibodies produced against the capsule often lead to phagocytosis and immunity against that bacterial strain.

Cell appendages

Flagella are exterior protein filaments that rotate and cause bacteria to be motile. Bacterial species differ in their possession of flagella from none (nonmotile) to many ([Fig. 1.4](#)). Flagella that extend from one end of the bacterial cell are polar. Polar flagella may occur singly at one end (*monotrichous*) or both ends (*amphitrichous*) or multiply in tufts at one end (*lophotrichous*). Flagella that occur all around the bacterium are *peritrichous*. The number and arrangement of flagella are sometimes used for identification purposes. Flagella can be visualized microscopically with special flagellum stains.

Pili (plural of *pilus*) and **fimbriae** (plural of *fimbria*) are nonflagellar, proteinaceous, hairlike appendages extending a short distance from the surface of some bacterial cells that adhere cells to one another and to host cells. *Conjugation pili* are protein tubes that connect two bacterial cells and mediate DNA exchange.

Fig. 1.4 Three flagellar arrangements found in bacteria. Other variations can occur.

Eukaryotic cell structure

The following structures are associated with eukaryotic cells (see [Table 1.1](#) and [Fig. 1.1](#)). In the diagnostic microbiology laboratory, medically important fungi and parasites have eukaryotic cells.

Cytoplasmic structures

The nucleus of the eukaryotic cell contains the DNA of the cell in the form of discrete chromosomes—structures in the nucleus that carry genetic information (genes)—contained within a nuclear membrane. Chromosomes are covered with basic proteins called *histones*. The number of chromosomes in the nucleus differs according to the particular organism. A rounded, refractile body called a *nucleolus* is also located within the nucleus. The nucleolus is the site of rRNA synthesis. The nucleus is bounded by a bilayered lipoprotein nuclear membrane.

The ER is a system of membranes found throughout the cytoplasm. It occurs in two forms. The “rough” ER is covered with ribosomes and is the site of protein synthesis. The ribosomes give the ER the rough appearance. The smooth ER does not have ribosomes on the outer surface of its membrane, hence its smooth appearance. Smooth ER does not synthesize proteins, but it does synthesize phospholipids. The major function of the Golgi apparatus or complex is to modify and package proteins and lipids sent to it by the ER.

Eukaryotic ribosomes, where protein synthesis occurs, are 80S in size and dissociate into two subunits: 60S and 40S. They are attached to the rough ER. Eukaryotic cells contain several membrane-enclosed organelles. Mitochondria are the main site of energy production. They contain DNA and the electron transport system that produces energy in the form of adenosine triphosphate (ATP). Lysosomes contain hydrolytic enzymes for degradation of macromolecules and microorganisms within the cell. Peroxisomes contain protective enzymes that break down hydrogen peroxide and other peroxides generated within the cell. Chloroplasts, found in plant cells, are the sites of photosynthesis. Chloroplasts are the sites where light energy is converted into chemical energy (ATP). Photosynthesis produces oxygen from carbon dioxide and water. Fungi are not plants and have no chloroplasts.

Cell envelope structures

Plasma membrane

The plasma membrane (see Fig. 1.2) is a phospholipid bilayer with embedded proteins that envelops the cytoplasm and regulates transport of macromolecules into and out of the cell. A substantial amount of cholesterol is found in the plasma membrane of animals. Cholesterol has a stabilizing effect and helps keep the membrane fluid. The polar heads of the phospholipids are hydrophilic (water loving) and lie on the intracellular and extracellular sides of the membrane; their nonpolar tails are hydrophobic (water hating) and avoid water by lining up in the center of the plasma membrane “tail to tail.” This type of hydrophobic makeup of the interior of the plasma membrane makes it potentially impermeable to water-soluble molecules. Proteins, embedded in the membrane, perform several important functions. They can act as enzymes, hormone receptors, pore channels, and carriers.

Cell wall

The function of a cell wall is to provide rigidity and strength to the exterior of the cell. Most eukaryotic cells do not have cell walls. However, fungi have cell walls principally made of polysaccharides, such as chitin, mannan, and glucan. Chitin is a distinct component of fungal cell walls.

Motility organelles

Cilia are short projections (3 to 10 μm), usually numerous, that extend from the cell surface and are used for locomotion. They are found in certain protozoa and in ciliated epithelial cells of the respiratory tract. Flagella are longer projections (>150 μm) used for locomotion by protozoa and animal cells such as spermatozoa.

Bacterial morphology

Microscopic shapes

The largest bacterium known, *Thiomargarita namibiensis*, is found in ocean sediment and generally has a diameter of 0.1 to 0.3 mm. Most bacteria range in size from 0.4 to 2 μm . They occur in three basic shapes (Fig. 1.5):

- Cocci (spherical)
- Bacilli (rod-shaped)
- Spirochetes (spiral)

Individual bacterial cells may form characteristic groupings. Cocci (plural of *coccus*) can occur singly, in pairs (diplococci), in chains (streptococci), or in clusters (staphylococci). Bacilli (plural of *bacillus*) vary greatly in size and length from very short coccobacilli to long filamentous rods. The ends may be square or rounded. Bacilli with tapered, pointed ends are termed **fusiform**; these cells are sometimes curved. When a species differs in size and shape within a pure culture, the bacterium is termed *pleomorphic*. Bacilli can occur as single rods or in chains or may align themselves side by side (palisades) or be branching. Spirochetes vary in length and in the number of helical turns; not all helical bacteria are called *spirochetes*.

Microscopic Morphology of Bacteria

Fig. 1.5 The microscopic shapes and arrangements of bacteria.

Common stains used for microscopic visualization

Stains that impart color or fluorescence are needed to visualize microscopically bacteria. The microscopic staining characteristics (i.e., shapes and groupings) are used in the classification and identification of microorganisms (Fig. 1.6).

Gram stain

The Gram stain is the most commonly used stain in the clinical microbiology laboratory. It places bacteria into one of two groups: gram-positive (blue to purple) or gram-negative (pink or red; see Fig. 1.6A–B). Some organisms are gram-variable or do not stain at all. As mentioned previously, the cell wall structure determines the Gram-staining characteristics. The Gram stain consists of gentle heat fixing (methyl alcohol may be used instead for fixation) of the smear and the addition of four sequential components: crystal violet (the primary stain, 1 minute), iodine (the mordant or fixative, 1 minute), alcohol or an alcohol-acetone solution (the decolorizer, a quick rinse), and safranin (the counterstain, 30 seconds). The time frames listed are not exact and vary with the organism; rinsing with water between each

Fig. 1.6 **A**, Gram stain of *Lactobacillus* species illustrating gram-positive bacilli, singly and in chains. A few gram-negative-staining bacilli are also present. **B**, Gram stain of *Escherichia coli* illustrating short gram-negative bacilli. **C**, Acid-fast stain, carbol fuchsin–based. Sputum smear demonstrating the presence of acid-fast *Mycobacterium* species (arrow) stained by the Kinyoun or Ziehl-Neelsen carbol fuchsin method. **D**, Acid-fast stain, fluorochrome–based. *Mycobacterium* species stained with the acid-fast fluorescent auramine-rhodamine stain. This stain is useful for screening for the presence of acid-fast bacteria in clinical specimens. **E**, Acridine orange stain. Fluorescent stain demonstrating the presence of staphylococci in a blood culture broth. This stain is useful for detecting bacteria in situations in which debris may mask the bacteria. **F**, Methylene blue stain. Methylene blue stain demonstrating the typical morphology of *Corynebacterium diphtheriae* (arrows). **G**, Lactophenol cotton blue stain. Lactophenol cotton blue–stained slide of macroconidia and hyphae of the fungal dermatophyte *Microsporum gypseum*. **H**, India ink. An India ink wet mount of the yeast *Cryptococcus neoformans* demonstrating the presence of a capsule (arrow). (A and B, Courtesy Dr. Andrew G. Smith, Baltimore, MD; D, courtesy Clinical Microbiology Audiovisual Study Units, Health and Education Resources, Inc., Bethesda, MD; E, courtesy Dr. John E. Peters, Baltimore, MD; and H, courtesy Dr. Andrew G. Smith, Baltimore, MD.)

step is important. The bacteria are initially stained purple by the crystal violet that is bound to the cell wall with the aid of iodine. When the decolorizer is applied to bacteria with a gram-negative cell wall, the crystal violet washes out of the cells, which then take up the pink counterstain, safranin. For this reason, gram-negative bacteria appear pink under the light microscope. Bacteria with a gram-positive cell wall retain the primary crystal violet stain during the decolorizing treatment and appear purple. Cells in a direct smear from a patient specimen, such as epithelial cells, white blood cells, red blood cells, and amorphous background material, should appear pink if the Gram stain procedure was performed correctly.

Case check 1.3

Review of quality control slides is important in detecting errors in the performance of the Gram stain procedure and in interpreting results. As illustrated in the Case in Point, the gram-positive control organism, *S. aureus*, stained gram-positive, which is an acceptable result. However, the gram-negative control organism, *E. coli*, also appeared gram-positive, which is an unacceptable result and indicative of an error in performing the Gram stain procedure. When such an error occurs, the results cannot be reported until the discrepancy is resolved, and the procedure is repeated with acceptable quality control results.

Acid-fast stains

Acid-fast stains are used to stain bacteria that have a high lipid (mycolic acid) and wax content in their cell walls and do not stain well with traditional bacterial stains. Carbol fuchsin, a red dye, is used as the primary stain (see Fig. 1.6C). Mycolic acid makes the bacterial cell resistant to acid-alcohol decolorization and hence the bacteria retain the primary stain. Mycobacteria, because they retain the stain, are designated acid-fast bacteria. The cell wall is treated to allow penetration of the dye either by heat (Ziehl-Neelsen method) or by a detergent (Kinyoun method). Acidified alcohol is used as a decolorizer, and methylene blue, or sometimes malachite green, is the counterstain. Acid-fast bacteria retain the primary stain and are pink. Bacteria that are not acid fast are blue or green depending on the counter stain. Two other gram-positive genera, *Nocardia* and *Rhodococcus*, may stain acid-fast by a modified method that utilizes a weaker decolorizer. They are generally considered partially acid-fast when stained with a modified acid-fast stain. In addition, the nocardiae give a darker blue appearance on Gram stain compared with the faint blue for mycobacteria. Acid-fast staining is also used to identify *Saccharomyces*, a yeast, and coccidian parasites, such as *Cystoisospora belli* (formerly known as *Isospora belli*), *Cryptosporidium*, and other coccidia like bodies.

A fluorochrome (i.e., fluorescent) stain, auramine-rhodamine, is also used to screen specimens for acid-fast bacteria (see Fig. 1.6D). This stain is selective for the cell wall of acid-fast bacteria. Acid-fast bacteria appear yellow or orange under a fluorescent microscope, making them easier to find and the staining method more sensitive than carbol fuchsin-based stains. Non-acid-fast bacteria are unstained.

Acridine orange

Acridine orange is a fluorochrome dye that stains gram-positive and gram-negative bacteria, living or dead. It binds to the nucleic acid of the cell and fluoresces a bright orange when a fluorescent microscope is used. Acridine orange is used to locate bacteria in blood cultures and other specimens in which discerning bacteria might otherwise be difficult (see Fig. 1.6E). Acridine orange will stain eukaryotic cells as well.

Calcofluor white

Calcofluor white is a fluorochrome that binds to chitin in fungal cell walls. It fluoresces a bright apple-green or blue-white, allowing visualization of fungal structures with a fluorescent microscope. Calcofluor white was the original “bluing” used in high-volume laundries to whiten yellow-appearing white cotton and other fabrics. See also Procedure 5 in Appendix D on Evolve.

Methylene blue

Methylene blue traditionally has been used to stain *Corynebacterium diphtheriae* for observation of metachromatic granules (see Fig. 1.6F). It is also used as a counterstain in acid-fast staining procedures. It is sometimes used as a simple stain to detect white blood cells, such as in stool samples.

Lactophenol cotton blue

Lactophenol cotton blue is used to stain the cell walls of medically important fungi grown in slide cultures (see Fig. 1.6G). It utilizes the blue dye aniline.

India ink

India ink and nigrosin are negative stains used to visualize capsules surrounding certain yeasts, such as the yeast *Cryptococcus* spp. (see Fig. 1.6H). The fine ink particles are excluded from the capsule, leaving a dark background and a clear capsule surrounding the yeast cells.

Endospore stain

The Schaefer-Fulton spore stain is used to stain bacterial spores. The primary stain, malachite green, is applied (flooded) to a heat-fixed smear and heated to steaming for about 5 minutes. Then the preparation is washed for about 30 seconds to remove the primary stain. Next, the counterstain safranin is applied to the smear. The endospores appear green within pink- or red-appearing bacterial cells.

Microbial growth and nutrition

All bacteria have three major nutritional needs for growth:

- A carbon source for making cellular constituents. Carbon represents 50% of the dry weight of a bacterium.
- A nitrogen source for making proteins and nucleic acids. Nitrogen makes up 14% of the dry weight.
- An energy source (ATP) for performing cellular functions.

Smaller amounts of molecules, such as phosphate for nucleic acids and phospholipids of cell membranes and sulfur for protein synthesis, make up an additional 4% of the weight. Various metals and ions for enzymatic activity must also be present in trace amounts. Important mineral ions, such as Na^+ , K^+ , Cl^- , Fe^{2+} , and Ca^{2+} , are also required. Although the basic building blocks required for growth are the same for all cells, bacteria differ widely in their ability to use different sources of these molecules.

Nutritional requirements for growth

Bacteria are classified into two groups according to how they meet their nutritional needs. The **autotrophs** (lithotrophs) are able to grow simply, using carbon dioxide as the sole source of carbon, in addition to the required water and inorganic salts. Autotrophs obtain energy either photosynthetically (phototrophs) or by oxidation of inorganic compounds (chemolithotrophs). Autotrophs occur in environmental milieus.

The second group of bacteria, the **heterotrophs**, require more complex substances for growth. These bacteria require an organic source of carbon, such as glucose, and obtain energy by oxidizing or fermenting organic substances. Often, the same substance (e.g., glucose) is used as both the carbon source and the energy source.

All bacteria that inhabit the human body are heterotrophs. However, nutritional needs differ greatly within this group. Bacteria such as *E. coli* and *Pseudomonas aeruginosa* can use a wide variety of organic compounds as carbon sources and grow on most simple laboratory media. Other pathogenic bacteria, such as *H. influenzae* and the anaerobes, are fastidious, requiring additional metabolites such as vitamins, purines, pyrimidines, and hemoglobin supplied in the growth medium. Some pathogenic bacteria, such as *Chlamydia* spp., cannot be cultured on laboratory media and must be grown in cell culture or detected by other means.

Types of growth media

Various types of growth media are used in the diagnostic microbiology laboratory to cultivate and recover bacteria from clinical samples. Culture media are categorized according to their function and ability to support growth. Those

that contain nutrients that support the growth of most non-fastidious organisms are called **nonselective** or **nutritive** type of media. Examples of nutrient media include trypticase soy agar or broth and nutrient agar. A growth medium that contains added growth factors, such as blood, vitamins, and yeast extract, is referred to as an **enriched** medium (e.g., sheep blood agar and chocolate agar). The added factors allow fastidious organisms to grow.

Media that contain additives such as dyes, bile salts, alcohols, acids, and antimicrobial agents that inhibit the growth of some bacteria but allow others to grow are called **selective media**. MacConkey (MAC) agar is an example of a selective medium for gram-negative bacteria. It contains bile salts and crystal violet that inhibit gram-positive bacteria but allow the growth of gram-negative bacteria. Columbia agar with colistin and nalidixic acid, alternatively, is selective for gram-positive organisms by inhibiting the growth of gram-negative bacteria. Media that contain ingredients that allow visualization of metabolic differences between groups or species of bacteria are called **differential media**. MAC agar, a selective medium, is also a differential medium because it distinguishes between lactose fermenters (pink colonies) and nonlactose fermenters (clear colonies) (Fig. 1.7A–B). Sheep blood agar, an enriched, nonselective type of medium, is also differential because it distinguishes between hemolytic and nonhemolytic organisms. Fig. 1.8 shows a sheep blood agar plate containing beta-hemolytic colonies. Therefore some media can be selective and differential (e.g., MAC agar) or nonselective and differential (e.g., sheep blood agar).

Broth media, such as thioglycollate broth, can be used to supplement agar media to recover small numbers of organisms that may be present in a clinical sample. **Enrichment broth** is designed to encourage the growth of small numbers of a particular organism while suppressing other bacteria that might be present in the specimen. An example is Lim broth (Todd Hewitt with colistin and nalidixic acid) used to enhance the growth of group B streptococci. Enrichment broths are incubated for a specific time and then must be subcultured to solid media to isolate the organism of interest.

When a delay between collection of the specimen and culturing is necessary, a **transport medium** is used. A transport medium is a holding medium designed to preserve the

Fig. 1.7 **A**, Lactose-fermenting, gram-negative rods producing pink colonies on MacConkey (MAC) agar. **B**, Nonlactose fermenting, gram-negative rods producing colorless colonies on MAC agar.

Fig. 1.8 Blood agar plate showing beta-hemolytic colonies.

viability of microorganisms in the specimen but not allow multiplication. Stuart broth and Amies and Cary-Blair transport media are commonly used examples.

Environmental factors influencing growth

The following three important environmental factors influence the growth rate of bacteria and must be considered when bacteria are cultured in the laboratory:

- pH
- Temperature
- Gaseous composition of the atmosphere

Most pathogenic bacteria grow best at a neutral pH. Diagnostic laboratory media for bacteria are usually adjusted to a final pH between 7.0 and 7.5. Temperature influences the rate of growth of a bacterial culture. Microorganisms are categorized according to their optimal temperature for growth. Bacteria that grow best at cold temperatures are called **psychrophiles** (optimal growth at 10° to 20° C). Bacteria that grow optimally at moderate temperatures are called **mesophiles** (optimal growth at 20° to 40° C). Bacteria that grow best at high temperatures are called **thermophiles** (optimal growth at 50° to 60° C). Psychrophiles and thermophiles are found environmentally in places such as the Arctic seas and hot springs, respectively. Most bacteria that have adapted to humans are mesophiles, which grow best near the human core body temperature of 37° C. Diagnostic laboratories routinely incubate cultures for bacterial growth at 35° C. However, some pathogenic species prefer a lower temperature for growth; when these organisms are suspected, the media from these specimens are incubated at a lower temperature. Fungal cultures are incubated at 30° C. The ability to grow at room temperature (22° C) or at an elevated temperature (42° C) is used as an identification characteristic for some bacteria.

Bacteria that infect humans differ in their atmospheric requirements for growth. In the diagnostic microbiology laboratory, bacterial atmospheric growth requirements are optimized to ensure recovery and isolation of pathogenic organisms from clinical samples. Microorganisms that require oxygen for growth are called **obligate aerobes**, and those that cannot grow in the presence of oxygen are

obligate or **strict anaerobes**. Obligate anaerobes must be grown in an atmosphere either devoid of oxygen or with significantly reduced oxygen content. **Aerotolerant anaerobes** can survive in the presence of oxygen but grow poorly and do not use oxygen in metabolism; **facultative anaerobes** can grow either with or without oxygen. If oxygen is present, the facultatively anaerobic bacteria will utilize it via aerobic respiration and grow faster than without oxygen. Facultative anaerobes like *E. coli* are routinely cultured in an aerobic atmosphere because aerobic culture is easier and less expensive than anaerobic culture, and the bacteria grow more rapidly.

Microaerophilic bacteria require a reduced level of oxygen to grow. An example of a pathogenic microaerophile is *Campylobacter jejuni*, which requires 5% to 6% oxygen. The atmosphere required by microaerophiles can be generated in culture jars or pouches with a commercially available microaerophilic atmosphere-generating system.

Capnophilic organisms are those that require an atmosphere enriched with carbon dioxide (5% to 10%); an example is *Neisseria gonorrhoeae*. The concentration of carbon dioxide in ambient air is about 400 parts per million. Air contains approximately 21% oxygen. When the carbon dioxide content of an aerobic incubator is increased to 10%, the oxygen content of the incubator is decreased to approximately 18%. Obligate aerobes must have oxygen to grow; incubation in air or an aerobic incubator with 10% carbon dioxide satisfies their oxygen requirement. Because many bacteria grow better in the presence of increased carbon dioxide, diagnostic microbiology laboratories often maintain their aerobic incubators at a 5% to 10% carbon dioxide level, in what is commonly referred to as a *carbon dioxide incubator*.

Bacterial growth

Generation time

Bacteria replicate by binary fission, with one cell dividing into two cells. The time required for one cell to divide into two cells is called the *generation time* or *doubling time*. The generation time of a bacterium in culture can be 20 minutes for a fast-growing bacterium such as *E. coli* or 24 hours for a slow-growing bacterium such as *Mycobacterium tuberculosis*.

Growth curve

If bacteria are in a growth state with enough nutrients and no toxic products present, the increase in bacterial numbers is proportional to the increase in other bacterial properties, such as mass, protein content, and nucleic acid content. Measurement of any of these properties can be used as an indication of bacterial growth. When the growth of a bacterial culture (number of live cells) is plotted over time, the resulting growth curve shows four phases of growth: (1) a lag phase in which bacteria are preparing to divide; (2) an exponential phase in which bacterial numbers increase logarithmically; (3) a stationary phase in which nutrients are becoming limited and the numbers of bacteria remain constant (although viability may decrease); and (4) a death phase in which the number of nonviable bacterial cells exceeds the

number of viable cells. An example of such a growth curve is shown in Fig. 1.9.

Determination of cell numbers

In the diagnostic laboratory, the number of bacterial cells present is determined in one of three ways:

- *Direct counting under the microscope:* This method can be used to estimate the number of bacteria present in a specimen. It does not distinguish between live and dead cells.
- *Direct plate count:* By growing dilutions of broth cultures on agar plates, one can determine the number of colony-forming units per milliliter (CFU/mL). This method provides a count of viable cells only. It is used in determining the bacterial cell count in urine cultures.
- *Density measurement:* The density (referred to as turbidity) of a bacterial broth culture can be correlated to the number of CFU/mL of the culture. This method is used to prepare a standard inoculum for antimicrobial susceptibility testing.

Fig. 1.9 Typical growth curve of a bacterial culture.

Bacterial biochemistry and metabolism

Metabolism

Microbial metabolism consists of the biochemical reactions bacteria use to break down organic compounds (catabolism) and the reactions they use to synthesize new molecules (anabolism) from smaller subunits. Energy for anabolism is generated during catabolism of a substrate. The occurrence of all biochemical reactions in the cell depends on the presence and activity of enzymes. Thus metabolism can be regulated in the cell either by regulation of the production of an enzyme itself (a genetic type of regulation in which production of the enzyme can be induced or suppressed by molecules present in the cell) or by regulation of the activity of the enzyme (via feedback inhibition in which the products of the enzymatic reaction or a succeeding enzymatic reaction inhibit the activity of the enzyme).

Bacteria differ widely in their ability to use various compounds as substrates and in the end products generated. Many biochemical pathways exist for catabolism in the microbial world, and the particular pathway used determines the end product and resulting pH of the medium (Fig. 1.10). Microbiologists use these metabolic differences as phenotypic markers in the identification of bacteria. Diagnostic schemes analyze each unknown microorganism for (1) utilization of various substrates as a carbon source, (2) production of specific end products from various substrates, and (3) production of an acid or alkaline pH in the test medium. Knowledge of the biochemistry and metabolism of bacteria is important in identifying microorganisms in the clinical laboratory.

Fermentation and respiration

Bacteria use biochemical pathways to catabolize carbohydrates and produce energy by two mechanisms—fermentation and aerobic respiration (commonly referred to as *oxidation*). **Fermentation** is an anaerobic process carried out by obligate, facultative, and aerotolerant anaerobes. In fermentation, the

Fig. 1.10 The fate of pyruvate in major fermentation pathways of microorganisms. (From Zinsser, H., et al. [1992]. *Zinsser microbiology* [20th ed]. Norwalk, CT: Appleton & Lange.)

electron acceptor is an organic compound. Fermentation is less efficient in energy generation than respiration because the beginning substrate is not completely reduced; therefore all of the energy in the substrate is not released.

Besides allowing growth in the absence of atmospheric oxygen, fermentation is also important because it generates nicotinamide adenine dinucleotide (NAD), a molecule necessary for maintaining the Krebs cycle. When fermentation occurs, a mixture of end products (e.g., lactate, butyrate, ethanol, and acetoin) accumulates in the medium. Analysis of these end products is particularly useful for the identification of anaerobic bacteria. End-product determination is also used in the Voges-Proskauer (VP) and methyl red tests, two important tests used in the identification of members of the order Enterobacterales. The term *fermentation* is often used loosely in the diagnostic microbiology laboratory to indicate any type of utilization—fermentative or oxidative—of a carbohydrate (sugar) with the resulting production of an acid pH.

Aerobic respiration (oxidation) is an efficient energy-generating process in which molecular oxygen (O_2) is the final electron acceptor. Obligate aerobes and facultative anaerobes undergo aerobic respiration. Some anaerobes can carry out anaerobic respiration in which molecules other than molecular oxygen, such as nitrate and sulfate, act as the final electron acceptors. Anaerobic respiration is less energy yielding than aerobic respiration.

Biochemical pathways from glucose to pyruvic acid

The starting carbohydrate for bacterial fermentation or oxidation is glucose. When bacteria use other sugars as a carbon source, they first convert the sugar to glucose, which is processed by one of three pathways. These pathways are designed to generate pyruvic acid, a key three-carbon intermediate. The three major biochemical pathways bacteria use to break down glucose to pyruvic acid are (1) the Embden-Meyerhof-Parnas (EMP) glycolytic pathway (Fig. 1.11), (2) the pentose phosphate pathway (Fig. 1.12), and (3) the Entner-Doudoroff pathway (see Fig. 1.12). Pyruvate can be further catabolized either fermentatively or oxidatively. The three major metabolic pathways and their key characteristics are described in Box 1.1.

Anaerobic utilization of pyruvic acid (fermentation)

Pyruvic acid is a key metabolic intermediate. Bacteria process pyruvic acid further using various fermentation pathways. Each pathway yields different end products, which can be analyzed and used as phenotypic markers (see Fig. 1.10). Some fermentation pathways used by the microbes that inhabit the human body are as follows:

- **Alcoholic fermentation:** The major end product is ethanol. This is the pathway used by yeasts when they ferment glucose.
- **Homolactic fermentation:** The end product is almost exclusively lactic acid. Members of the genus *Streptococcus* and

Fig. 1.11 Embden-Meyerhof-Parnas glycolytic pathway. (From Zinsser, H., et al. [1992]. *Zinsser microbiology* [20th ed]. Norwalk, CT: Appleton & Lange.)

many members of the genus *Lactobacillus* ferment pyruvate using this pathway.

- **Heterolactic fermentation:** Some lactobacilli use a mixed fermentation pathway, of which, in addition to lactic acid, the end products include carbon dioxide, alcohols, formic acid, and acetic acid.
- **Propionic acid fermentation:** Propionic acid is the major end product of fermentation carried out by *Cutibacterium acnes* (formerly *Propionibacterium acnes*) and some anaerobic non-spore-forming, gram-positive bacilli.
- **Mixed acid fermentation:** Members of the genera *Escherichia*, *Salmonella*, and *Shigella* within the order Enterobacterales use this pathway for carbohydrate fermentation and produce a number of acids as end products: lactic, acetic, succinic, and formic. The strong acid produced is the basis for the positive reaction on the methyl red test exhibited by these organisms and the acidic pH on laboratory media.
- **Butanediol fermentation:** Members of the genera *Klebsiella*, *Enterobacter*, and *Serratia* within the order Enterobacterales use this pathway for carbohydrate fermentation. The end products are acetoin (acetyl methyl carbinol) and 2,3-butanediol. Detection of acetoin is the basis for the positive VP reaction characteristic of these microorganisms. Little acid is produced by this pathway. Thus organisms that have a positive VP reaction usually have a negative methyl red test, and vice versa.
- **Butyric acid fermentation:** Certain obligate anaerobes, including many *Clostridium*, *Fusobacterium*, and *Eubacterium* species, produce butyric acid as their primary end product along with acetic acid, carbon dioxide, and hydrogen.

Fig. 1.12 Alternative microbial pathways to the Embden-Meyerhof-Parnas (EMP) pathway for glucose fermentation. The pentose phosphate pathway (*left*) and the Entner-Doudoroff pathway (*right*) are shown. (From Zinsser, H., et al. [1992]. *Zinsser microbiology* [20th ed]. Norwalk, CT: Appleton & Lange.)

BOX 1.1 Three major metabolic pathways found in bacteria

EMP glycolytic pathway (see Fig. 1.11)

- Major pathway in conversion of glucose to pyruvate
- Generates reducing power in the form of NADH_2
- Generates energy in the form of ATP
- Anaerobic; does not require oxygen
- Used by many bacteria, including all members of the order Enterobacterales

Pentose phosphate (phosphogluconate) pathway (see Fig. 1.12)

- Alternative to EMP pathway for carbohydrate metabolism
- Conversion of glucose to ribulose-5-phosphate, which is rearranged into other 3-, 4-, 5-, 6-, and 7-carbon sugars
- Provides pentoses for nucleotide synthesis
- Produces glyceraldehyde-3-phosphate, which can be converted to pyruvate

- Generates NADPH, which provides reducing power for biosynthetic reactions
- May be used to generate ATP (yield is less than with EMP pathway)
- Used by heterolactic fermenting bacteria, such as lactobacilli, and by *Brucella abortus*, which lacks some of the enzymes required in the EMP pathway

Entner-doudoroff pathway (see Fig. 1.12)

- Converts glucose-6-phosphate (rather than glucose) to pyruvate and glyceraldehyde phosphate, which can be funneled into other pathways
- Generates one NADPH per molecule of glucose, but uses one ATP
- Aerobic process used by *Pseudomonas*, *Alcaligenes*, *Enterococcus faecalis*, and other bacteria lacking certain glycolytic enzymes

ATP, Adenosine triphosphate; EMP, Embden-Meyerhof-Parnas; NADH_2 , nicotinamide adenine dinucleotide dehydrogenase; NADPH, nicotinamide adenine dinucleotide phosphate.

Aerobic utilization of pyruvate (oxidation)

The most important pathway for the complete oxidation of a substrate is the **Krebs cycle** or tricarboxylic acid cycle. In this cycle, the starting molecule, pyruvate, is oxidized, carbon skeletons for biosynthetic reactions are created,

guanosine-triphosphate (GTP) is generated, and electrons are donated to form NADH and FADH_2 , which ultimately enter the electron transport chain to generate energy in the form of ATP. This cycle results in the production of acid and the evolution of carbon dioxide during aerobic respiration (Fig. 1.13).

Fig. 1.13 Krebs tricarboxylic acid cycle allowing complete oxidation of a substrate. (From Zinsser, H., et al. (1992). *Zinsser microbiology* [20th ed]. Norwalk, CT: Appleton & Lange.)

Carbohydrate utilization and lactose fermentation

The ability of microorganisms to use various sugars (carbohydrates) for growth is an integral part of many identification schemes. The fermentation of the sugar is usually detected by acid production and a concomitant change of color resulting from a pH indicator present in the culture medium. Bacteria generally ferment glucose preferentially over other sugars, so glucose must be absent if the ability to ferment another sugar is being tested.

The microorganism's ability to ferment lactose is an important step in classifying members of the order Enterobacterales. These bacteria are classified as either lactose fermenters or nonlactose fermenters. Lactose is a disaccharide consisting of one molecule of glucose and one molecule of galactose linked by a galactoside bond. The utilization of lactose by a bacterium requires two steps. The first step requires the enzyme β -galactoside permease for the transport of lactose across the cell wall into the cytoplasm. The second step occurs inside the cell and requires the enzyme β -galactosidase to break the galactoside bond, releasing glucose, which then can be fermented. Thus all organisms that ferment lactose can also ferment glucose.

Microbial genetics

No discussion of microbial genetics is complete without first describing DNA and RNA. DNA was first discovered by Frederick Miescher in 1869. In the 1920s, Phoebus A. T. Levine discovered that DNA contained phosphates, five-carbon sugars (cyclic pentose), and nitrogen-containing bases. Later, Rosalind Franklin discovered the helical structure by x-ray crystallography. Most everyone is familiar with James Watson and Francis Crick, who described the three-dimensional structure of the DNA molecule in the 1950s.

Anatomy of a DNA and RNA molecule

DNA is a double-helical chain of deoxynucleotides. The helix is a double strand twisted together, which many scientists refer to as a *spiral staircase* (resembling the handrail, sides, and steps of a spiral staircase). A nucleotide is a complex combination of the following:

- A phosphate group (PO_4)
- A cyclic five-carbon pentose (the carbons in the pentose are numbered 1' to 5') sugar (deoxyribose), which makes up the "handrails and sides"
- A nitrogen-containing base, or the "steps," either a purine or a pyrimidine

A purine consists of a fused ring of nine carbon atoms and nitrogen. There are two purines in DNA: adenine (A) and guanine (G). A pyrimidine consists of a single ring of six atoms of carbon and nitrogen. There are two pyrimidines in DNA: thymine (T) and cytosine (C). A nucleotide is formed when the 5' carbon of the sugar and one of the nitrogenous bases attaches to the 1' carbon of the pentose sugar. These are the basic building blocks of DNA (Fig. 1.14).

In the chain of deoxynucleotides, bonds form between the phosphate group of one nucleotide and the 3' sugar of the next nucleotide. The base extends from the sugar. Adenine of one chain always pairs with thymine of the other chain, and cytosine of one chain pairs with guanine of the other chain. The bases are held together by hydrogen bonds. The information contained in DNA is determined by the sequence of letters along the "staircase." The sequence ACGCT represents different information than the sequence AGTCC. This would be like taking the word *stops* and using the same letters to form the word *spots* or *posts*, which have different meanings but all of the same letters.

The two complementary sugar phosphate strands run in opposite directions (antiparallel), 3' to 5' and 5' to 3', similar to one train with its engine going one way alongside a caboose of a train going the opposite direction (Fig. 1.15). The direction is based on what is found at the ends of the strands; for example, phosphate attaches to the 5' carbon of the sugar, and the OH group is attached to the 3' carbon of the sugar.

DNA is used as a template to produce the complementary messenger RNA (mRNA) strand. In RNA, the nitrogenous base thymine is replaced by uracil, another pyrimidine. In contrast with DNA, RNA is single-stranded and short, not double-stranded and long, and it contains the sugar ribose, not deoxyribose.

Fig. 1.14 Molecular structure of nucleic acid bases. Pyrimidines: cytosine, thymine, and uracil. Purines: adenine and guanine.

Fig. 1.15 A, Molecular structure of DNA showing nucleotide structure, a phosphodiester bond connecting nucleotides, and complementary pairing of bases (A, adenine; T, thymine; G, guanine; C, cytosine) between antiparallel nucleic acid strands. **B**, 5' and 3' antiparallel polarity and “twisted ladder” configuration of DNA.

Humans are 99.9% identical. In a human genome of 3 billion “letters,” even one tenth of 1% translates into 3 million separate lettering differences, an important characteristic useful in forensic science. Microbial genetics is increasingly important in the diagnostic microbiology laboratory. Identification tests have been developed that are based on identifying unique RNA or DNA sequences present in each bacterial species and viruses. The polymerase chain reaction technique is a means of amplifying specific DNA sequences and detecting very small numbers of bacteria present in a specimen. Genetic tests circumvent the need to culture bacteria, providing a more rapid method of identifying pathogens.

An understanding of microbial genetics is also necessary to understand the development and transfer of antimicrobial resistance by bacteria and mutations in viruses. Viruses constantly change, as in the case of the recently identified SARS-CoV-2 (severe acute respiratory syndrome–coronavirus-2), the virus that causes COVID-19 (Coronavirus Disease 2019). COVID-19 is the respiratory illness responsible for the COVID-19 pandemic that began in 2020. The occurrence of mutations can result in a change in the expected phenotypic characteristics of an organism and provides an explanation for atypical results sometimes encountered on diagnostic biochemical tests. For example, mutations in the SARS-CoV-2 virus present in a patient specimen can potentially affect test performance influenced by the sequence of the variant, the design of the test, and the prevalence of the variant in the population. To learn more about the newly identified SARS-CoV-2 virus, see [Chapter 29](#).

This section briefly reviews some of the basic terminology and concepts of microbial genetics. For a detailed discussion of DNA and molecular diagnostics, see [Chapter 11](#).

Terminology

The genotype of a cell is the genetic potential of the DNA of an organism. It includes all of the characteristics that are coded for in the DNA of a cell and that have the potential to be expressed. Some genes are silent genes, expressed only under certain conditions. Genes that are always expressed are *constitutive*. Genes that are expressed only under certain conditions are *inducible*. The phenotype of a cell consists of observed characteristics expressed by the genome. The aim of a cell is to produce proteins that are needed for cellular structure and function and to transmit that information for accomplishing this to the next generation of cells. Information for protein synthesis is encoded in the DNA and transmitted in the chromosome to each generation. The general flow of information in a cell is from DNA (which contains the genetic information) to mRNA, which acts as a blueprint for protein construction.

Replication is the duplication of chromosomal DNA for insertion into a daughter cell. **Transcription** is the synthesis of mRNA by the enzyme RNA polymerase using one strand of DNA as a template. **Translation** is the synthesis of a specific protein from the mRNA code. The term **protein expression** also refers to the synthesis of a protein. Proteins are polypeptides composed of amino acids. The number and sequence of amino acids in a polypeptide and the character

of that particular protein are determined by the sequence of codons in the mRNA molecule. A **codon** is a group of three nucleotides in an mRNA molecule that signifies a specific amino acid. During translation, ribosomes containing rRNA sequentially add amino acids to the growing polypeptide chain. These amino acids are brought to the ribosome by transfer RNA (tRNA) molecules that “translate” the codons. The tRNA molecules temporarily attach to mRNA using their complementary anticodon regions. An **anticodon** is the triplet of bases on the tRNA that bind the triplet of bases (codon) on the mRNA. It identifies which amino acid will be in a specific location in the protein.

Genetic elements and alterations

Bacterial genome

The bacterial chromosome, also called the *genome*, consists of a single, closed, circular piece of dsDNA that is supercoiled to fit inside the cell. It contains all of the information needed for cell growth and replication. Genes are specific DNA sequences that code for the amino acid sequence in one protein (e.g., one gene equals one polypeptide), but this may be sliced or combined with other polypeptides to form more than one protein. In front of each gene on the DNA strand is an untranscribed area containing a promoter region, which the RNA polymerase recognizes and binds to for transcription initiation. This area may also contain regulatory regions to which molecules may attach and cause either a decrease or an increase in transcription.

Extrachromosomal DNA elements

In addition to the genetic information encoded in the bacterial chromosome, many bacteria contain additional information on small circular pieces of *extrachromosomal* dsDNA called **plasmids**. They are *not* essential for bacterial growth, so they can be gained or lost. Genes that code for antimicrobial resistance (and sometimes toxins or other virulence factors) are often located on plasmids. Antimicrobial therapy selects for bacterial strains containing plasmids encoding drug-resistance genes; this is one reason antimicrobial agents should not be overprescribed. The number of plasmids present in a bacterial cell may range from one (low copy number) to hundreds (high copy number). Plasmids are located in the cytoplasm of the cell and are self-replicating and passed to daughter cells, similar to chromosomal DNA. They also may sometimes be passed from one bacterial cell to another through **conjugation** (horizontal transfer of genetic material by cell-to-cell contact). This is one way drug resistance is acquired.

Mobile genetic elements

Some fragments of DNA are mobile and can jump from one place in the chromosome to another place. These are sometimes referred to as *jumping genes*. The simplest mobile piece of DNA is an insertion sequence (IS) element. It is approximately 1000 base pairs long with inverted repeats on each end. Each IS element codes for only one gene, a transposase enzyme that allows the IS element to pop into and out of

DNA. Bacterial genomes contain many IS elements. The main effect of IS elements in bacteria is that when an IS element inserts itself into the middle of a gene, it disrupts and inactivates the gene. This action can result in loss of an observable characteristic, such as the ability to ferment a particular sugar. Transposons are related mobile elements that contain additional genes. Transposons often carry drug-resistance genes and are usually located in plasmids.

Mutations

Mutations are changes that occur in the DNA code and often result in a change in the coded protein or in the prevention of its synthesis. Some mutations are silent, in which a change in the DNA sequence does not result in the substitution of a different amino acid in the resulting protein. This is caused by redundancy in protein synthesis; more than one codon codes for the same amino acid. A mutation may be the result of a change in one nucleotide base (a point mutation) that leads to a change in a single amino acid within a protein (missense mutation) or may be the result of insertions or deletions in the genome that lead to disruption of the gene or a frameshift mutation, or both. A gene sequence must be read in the right “frame,” or series of three codons, for the correct protein to be produced. This is because every set of three bases in mRNA (a codon) specifies a particular amino acid, and when the reading frame is shifted, the codons are also shifted. Incomplete, inactive proteins are often the result of frameshift mutations. Some codons do not code for an amino acid; they terminate translation and are called *stop codons*. If a point mutation produces a stop codon, this is referred to as a *nonsense mutation*. Spontaneous mutations occur in bacteria at a rate of about 1 in 10^9 cells. Mutations also occur as the result of error during DNA replication at a rate of about 1 in 10^7 cells. Exposure to certain chemical and physical agents can greatly increase the mutation rate.

Genetic recombination

Genetic recombination is a method by which genes are transferred or exchanged between homologous (similar) regions on two DNA molecules, forming new combinations of genes on a chromosome. This provides a way for organisms to obtain new combinations of biochemical pathways and adapt to changes in their environment.

Mechanisms of gene transfer

Genetic material may be transferred from one bacterium to another in three ways:

- Transformation
- Transduction
- Conjugation

Transformation

Transformation is the uptake and incorporation of free or naked DNA into a bacterial cell (Fig. 1.16A). Once the DNA has been taken up, it can be incorporated into the bacterial genome by recombination. If the DNA is a circular plasmid

Fig. 1.16 Methods of gene transfer into bacterial cells. **A**, Bacterial transformation. Free or “naked” DNA is taken up by a competent bacterial cell. After uptake, the DNA may take one of three courses: (1) it is integrated into existing bacterial genetic material; (2) it is degraded; or (3) if it is a compatible plasmid, it may replicate in the cytoplasm. **B**, Bacterial transduction. A phage injects DNA into the bacterial cell. The phage tail binds to a receptor of the bacterial cell wall and injects the DNA into the bacterium. One of two courses may then occur. In the lytic cycle, replication of the bacterial chromosome is disrupted; phage components are formed and assembled into phage particles. The bacterial cell is lysed, releasing a mature phage. In the lysogenic cycle, the phage DNA is incorporated into the bacterial genetic material, and genes encoded by the phage DNA can be expressed. At a later time, the phage may be “induced,” and a lytic cycle then ensues. **C**, Bacterial conjugation. An F+ cell connects with an F- cell via sex pili. DNA is then transferred from the F+ cell to the F- cell.

and the recipient cell is compatible, the plasmid can replicate in the cytoplasm and be transferred to daughter cells during cell division. Cells that can take up naked DNA are referred to as being **competent**. Transformation is not an efficient process and has been reported to occur naturally in only a few bacterial species, such as *S. pneumoniae*, *N. gonorrhoeae*, *Helicobacter pylori*, and *H. influenzae*. Bacteria in biofilms have an increased rate of transformation compared with bacteria in the planktonic state. Bacteria can be made competent in the laboratory, and transformation is the main method used to introduce genetically manipulated plasmids into bacteria, such as *E. coli*, during cloning procedures.

Transduction

Transduction is the transfer of bacterial genes by a bacteriophage from one cell to another (see Fig. 1.16B). A bacteriophage consists of genetic material (DNA or RNA) surrounded

by a protein coat. When a phage infects a bacterial cell, it injects its genome into the bacterial cell, leaving the protein coat outside. The phage can then take a lytic pathway in which the bacteriophage DNA directs the bacterial cell to synthesize the phage genome and proteins and package it into new phage particles. The bacterial cell eventually lyses (lytic phase), releasing new phage particles that can infect other bacterial cells.

In some instances, the phage DNA instead becomes incorporated into the bacterial genome, where it is replicated along with the bacterial chromosomal DNA when the cell divides. This state is known as **lysogeny**, and the phage is referred to as being **temperate**. During lysogeny, genes present in the phage DNA may be expressed by the bacterial cell. An example of this in clinical microbiology is *C. diphtheriae*. Strains of *C. diphtheriae* that are lysogenized with a temperate phage carrying the gene for diphtheria toxin cause disease. Strains lacking the phage DNA do not produce the toxin and do not cause disease.

Under certain conditions, a temperate phage can be induced, the phage DNA is excised from the bacterial genome, and a lytic state occurs. During this process, adjacent bacterial genes may be excised with the phage DNA and packaged into the new phages. The bacterial genes may be transferred when the phage infects a new bacterium. In the field of biotechnology, phages are often used to insert cloned genes into bacteria for analysis.

Conjugation

Conjugation is the transfer of genetic material from a donor bacterial strain to a recipient strain (see Fig. 1.16C). Close contact is required between the two cells. In *E. coli*, the donor strain (F+) possesses fertility factor (F factor) on a plasmid that carries the genes for conjugative transfer. The donor strain produces a hollow surface appendage called a *sex* or *conjugation pilus*, which binds to the recipient F− cell and brings the two cells in close contact. Transfer of DNA then occurs. Both plasmids and chromosomal genes can be transferred by this method. When the F factor is integrated into the bacterial chromosome rather than a plasmid, there is a higher frequency of transfer of adjacent bacterial chromosomal genes. These strains are known as *high-frequency recombination strains*.

Restriction enzymes

Bacteria have evolved a system to restrict the incorporation of foreign DNA into their genomes. **Restriction enzymes** are produced that cut (restrict) incoming, foreign DNA at specific DNA sequences. The bacteria methylate their own DNA at these same sequences, so the restriction enzymes do not cut the DNA in their own cell. Many restriction enzymes with various recognition sequences have been isolated from various microorganisms. The first three letters in the restriction endonuclease name indicate the bacterial source of the enzyme. For instance, the enzyme *EcoRI* was isolated from *E. coli*, and the enzyme *Hind III* was isolated from *H. influenzae* type d. These enzymes are used in the field of biotechnology to create sites for insertion of new genes.

POINTS TO REMEMBER

- Many microorganisms inhabit the environment, and most are nonpathogenic.
- Prokaryotes, such as bacteria, do not have membrane-enclosed nuclei and organelles.
- Eukaryotes differ from prokaryotes in that they have membrane-enclosed nuclei and organelles.
- Viruses cannot be seen under an ordinary light microscope, although their cytopathic effects on cell cultures are visible. They are obligate parasites, and antimicrobial agents are ineffective for treatment of viral infections. Viruses have DNA or RNA, but rarely both, in contrast with prokaryotes and eukaryotes.
- In the diagnostic microbiology laboratory, the first step in identifying bacteria is by the Gram stain reaction. Whether an organism is gram-positive (blue or purple) or gram-negative (pink or red) depends on its cell wall structure. A thick peptidoglycan layer is present in gram-positive bacteria, while an outer membrane and thin peptidoglycan layer are found in gram-negative bacteria.
- Bacterial spores are formed because of harsh environments. They are a means of survival, not reproduction.
- The LPS contained in the outer membrane of gram-negative bacteria consists of three regions: an antigenic O-specific polysaccharide, a core polysaccharide, and an inner lipid A (also called *endotoxin*). The lipid A moiety is responsible for producing fever and shock conditions in patients infected with gram-negative bacteria.
- Based on atmospheric requirements, bacteria are classified as obligate aerobes, obligate anaerobes, facultative anaerobes, aerotolerant anaerobes, or microaerophiles.
- Bacteria utilize two biochemical pathways, fermentation and oxidation (aerobic respiration), to catabolize carbohydrates to produce energy.
- The three mechanisms by which genetic material may be transferred from one bacterium to another are transformation, transduction, and conjugation.

LEARNING ASSESSMENT QUESTIONS

1. Explain why the laboratory scientist in the Case in Point should repeat the Gram stain procedure on the exudate.
2. What might have occurred to make the Gram stain results invalid?
3. Differentiate the role of pili from the role of flagella.
4. What is the role of the bacterial capsule in the pathogenesis of infectious diseases?
5. Why is lipopolysaccharide (LPS) a significant outer-membrane structure in gram-negative bacteria?
6. A bacterium that grows only on plates incubated in the absence of oxygen would be categorized as a(n):
 - a. Aerotolerant anaerobe.
 - b. Facultative anaerobe.
 - c. Obligate anaerobe.
 - d. Obligate aerobe.
7. Fimbriae present on the outer surface of bacteria are used for:
 - a. Adherence to surfaces.
 - b. Antimicrobial resistance.
 - c. Sexual reproduction.
 - d. Bacterial motility.

8. All of the following are characteristic of fermentation *except*:
 - a. It begins with the breakdown of pyruvic acid.
 - b. It follows glycolysis and produces reduced nicotinamide adenine dinucleotide (NADH).
 - c. It produces acids, alcohols, and gases.
 - d. It can occur in the presence of oxygen.
9. Why are older bacterial cells more easily decolorized than cells from younger colonies?
10. Why are spore-forming organisms more resistant to environmental stress than non-spore-forming species?
11. Explain the three ways in which genetic material can be transferred from one bacterium to another.
12. For the following DNA, write the complementary sequence. Include labeling the 3' and 5' end. 3' TTACGGACAAC 5':
_____.
13. In RNA, thymine is replaced by _____.
14. In bacteriophage, how does lysogeny differ from the lytic cycle?
15. Nutrient and trypticase soy broths are culture media that are used primarily to satisfy the growth requirements of bacteria and support the growth of most nonfastidious organisms. This type of media is classified as:
 - a. Nutritive.
 - b. Selective.
 - c. Differential.
 - d. Enriched.
16. A patient was seen in the emergency department with fever and symptoms of disseminated intravascular coagulation, sepsis, and shock. Blood cultures taken from the patient grew gram-negative bacteria. Which of the following cellular structures might be responsible for this condition?
 - a. Pili
 - b. Capsule
 - c. Endotoxin
 - d. Spore
17. Which of the following best describes an organism that cannot use oxygen but will not be killed by oxygen if exposed to it?
 - a. Aerotolerant anaerobe
 - b. Obligate anaerobe
 - c. Facultative anaerobe
 - d. Obligate aerobe
18. An encapsulated organism is considered to be virulent because it can mediate which of the following?
 - a. Form spore
 - b. Inhibit phagocytosis
 - c. Increase mutation rate
 - d. Enhance motility

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Define the following terms: *parasitism*, *indigenous biota*, *commensal*, *symbiont*, *opportunist*, *transient biota*, *carrier*, *true pathogen*, *opportunistic pathogen*, *virulence*, and *zoonosis*.
2. Explain how the following factors determine the composition of the microbial biota at various body sites:
 - Amounts and types of nutrients available in the environment
 - pH
 - Oxidation-reduction potential
 - Resistance to antibacterial substances
3. List the predominant microbiota of various body sites in a healthy individual.
4. Evaluate the role of the indigenous microbiota in the pathogenesis of infectious disease.
5. Evaluate the role of the indigenous biota in host defense against infectious diseases.
6. Differentiate the mechanisms of infections caused by true pathogens from infections caused by opportunistic pathogens.
7. Name the routes of transmission that microorganisms use to initiate infection in a host, and give examples of each.
8. Discuss the conditions that must be present or events that must occur for a microorganism to cause disease.
9. Describe the characteristics of infectious agents that enable them to cause disease in the host.
10. Describe the innate and adaptive factors and mechanisms by which the human host is protected from microbial invasion.
11. Discuss the sequence of events in the phagocytosis and killing of an infectious agent.
12. Correlate a specific immune deficiency with the outcome to the host in preventing infectious diseases.

KEY TERMS

Adaptive immunity
Adhesin

Anamnestic immune response
Antibody

Antigen	Innate immunity
Bacteriocin	Interferon
Carrier	Lactoferrin
Carrier state	Leukocidin
Cell-mediated immune response	Lymphocyte
Chemotactic agent	Lymphokine
Chemotaxis	Lysozyme
Colonization	Mutualism
Commensalism	Opportunists
Complement system	Opsonin
Diapedesis	Opsonization
Dissemination	Parasite
Endotoxin	Parasitism
Exotoxin	Pathogen
Fimbriae	Pathogenicity
Fomites	Pattern recognition receptor
Humoral immune response	Phagocyte
Iatrogenic infection	Phagocytosis
Immune response	Pili
Immune system	Receptor
Immunogen	Resident microbial biota
Immunoglobulin A (IgA)	Respiratory burst
Immunoglobulin D (IgD)	Symbiosis
Immunoglobulin E (IgE)	Toll-like receptor
Immunoglobulin G (IgG)	Transient microbial biota
Immunoglobulin M (IgM)	Virulence
Immunoglobulins	Zoonoses
Indigenous microbiota	

Case in point

A 71-year-old male patient was treated for right lower extremity cellulitis with a 10-day course of the antibiotic cephalexin. A few days after completing the antibiotic course, he started having loose, watery diarrhea. The patient described having many episodes of diarrhea per day; after 3 days of diarrhea, he came to the emergency department. He also said that he had developed right quadrant abdominal pain over the past 24 hours. While in the emergency department, the patient had five episodes of loose, watery diarrhea. A bacterial culture of the stool was negative for *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, and *Vibrio* species, but a polymerase chain reaction assay for the *Clostridioides difficile* toxin B gene was positive.

Issues to consider:

After reading the patient's case history, consider:

- Factors that predisposed this patient to his current condition
- Clues that indicate the source of the infection
- Significance of the microbiota in protecting the host against pathogenic organisms
- Role of the host's innate and acquired immunity in protecting the host from infection
- Significance of microbial virulence factors in promoting infection

The outcome from the interactions between host and **pathogen**, a disease-causing agent, is influenced by numerous factors. The status of the host's immune system and ability of the host to defend itself from microbial and viral invasion, combined

with microbial and viral factors inherent to the invading pathogen, often determine whether disease occurs. To appreciate and understand the concepts involved in the pathogenesis of infectious diseases, knowledge and understanding of the host-pathogen relationship is important.

It is beyond the scope of this book to provide a detailed discussion of the complexities of the immune response. This chapter provides an overview by describing the interactions between the host and infectious agents in the pathogenesis of disease. The first part of the chapter describes the origin of the indigenous (resident) microbial biota (microbiota) and the composition at different body sites. It presents the role of the microbial biota at each body site in the host immune defense and as a source of opportunistic infections. Factors that determine the composition of the microbiota at different body sites are described. The second part of the chapter discusses the virulence factors that contribute to the invasiveness of organisms, protective mechanisms the host employs, and how microbes can evade the host's defenses. Lastly, this chapter describes factors that can make the host more susceptible to infections and how microbes are transmitted.

Origin of microbial biota

The fetus is in a sterile environment. During delivery and the first few days of life, the newborn is introduced to the many and varied microorganisms present in the environment. Many organisms can find an area on or in the infant into which they can adapt. Microorganisms that find their niche colonize various anatomic sites and become the predominant organisms. **Colonization** is growth of microbiota in or on a body site without the production of damage or notable symptoms. Other microorganisms are transient or fail to establish themselves at all. As the infant grows, the microbial biota eventually resemble the microbiota seen in older individuals.

Once established onto or into a particular body site of the host, microorganisms develop a particular relationship, or **symbiosis**, with that host. *Symbiosis* is defined as the association of two organisms of different species living together. The organisms are called *symbionts*. The host-microbe relationship, depending on the circumstance, may be one of **commensalism**, **mutualism**, or **parasitism**. Symbiosis as a biological relationship in which both (host and organism) benefit from one another may be described as *mutualism*. Lactobacilli in the urogenital tract of women offer a mutual association: the lactobacilli provide the host protection by preventing colonization of pathogenic species at that site while they derive nutrients from the host. In the relationship in which the organism benefits but there is no beneficial or harmful effect on the host, the association is called *commensalism*. *Klebsiella pneumoniae* is a commensal species in the gastrointestinal tract of humans. In parasitism, one species (parasite) benefits at the expense of the other (host). The parasite *Entamoeba histolytica* is a pathogenic intestinal amoeba that derives nutrients from the host at the expense of the host, causing intestinal ulcers and amebic dysentery.

Characteristics of indigenous microbial biota

Microorganisms that are commonly found on or in body sites of healthy persons are called *normal* or **indigenous microbiota**. The different body sites may have the same or different microbiota,

depending on conditions. Local conditions select for organisms that are suited for growth in a particular area. For example, the environment found on the dry skin surface is different from the environment found on the moist surfaces in the oral cavity; therefore the microbiota are different at the two sites.

Microorganisms that colonize an area for months or years represent **resident microbiota**, whereas microorganisms that are present at a site temporarily, for a shorter period, represent **transient microbiota**. Transient microbiota come to “visit” but do not stay. These microorganisms are eliminated either by the host-inherent immune defenses or by competition with the resident biota. Some pathogenic organisms may establish themselves in a host without manifesting symptoms. However, these hosts, called carriers, can transmit the infectious agent. The condition of these hosts is called the carrier state. The carrier state may be acute (short-lived) or chronic (lasting for months, years, or permanently). An example of a chronic carrier state is found in post-*Salmonella* Typhi infection. This organism can establish itself in the bile duct and can be excreted in the stool over years. In contrast, *Neisseria meningitidis* can be found in the nasopharynx of asymptomatic individuals during an outbreak of meningitis. After a few days or weeks at most, these individuals may no longer harbor the organism, in which case the carrier state would be termed *acute*. The most transient of carrier states is the inoculation of a person’s hands or fingers with an organism, for example, *Staphylococcus aureus* that has colonized the person’s anterior nares and is transmitted to the hands, that is carried only until the hands are washed.

The organisms colonizing different body sites play a significant role in providing host resistance to infections. The efficiency of the microbial biota in providing protection to the human host is indicated by the relatively small number of infections caused by these organisms in immunocompetent individuals. Nevertheless, these organisms may cause significant, often serious, infections or may exacerbate existing infections in individuals who are immunocompromised. Knowing the benefit of the normal microbiota, individuals can ingest probiotics, a suspension of live bacteria that normally colonize the gastrointestinal tract, to reestablish the microbiota. This is useful in some patients who have taken oral broad-spectrum antimicrobial agents that have reduced the number of resident bacteria in the intestines.

Factors that determine the composition of the usual microbial biota

Which microorganisms are present at a particular body site is influenced by nutritional and environmental factors, such as the amount and types of nutrients available at the site. For example, more organisms inhabit moist areas than dry areas. Moist skin areas are dominated by diphtheroids, nonpathogenic corynebacteria. Although lipids and fatty acids are bactericidal to most bacteria, *Propionibacterium* spp. colonize the ducts of hair follicles because these bacteria can break down the skin lipids to fatty acids. The affinity of microorganisms for a specific site depends on the ability of the organisms to resist the antibacterial effects of substances such as fatty acids, bile, or lysozyme. The composition of the microbial biota is also affected by pH. For example, the female genital tract microbiota depends on the pH of that environment, which in women

of childbearing age is approximately 4.0 to 5.0. Many bacteria do not survive at this extreme pH range. Another example is the fecal biota found in infants who are breast-fed, which differs from the fecal biota in infants fed with cow’s milk. Human milk has a high lactose concentration and maintains a pH of 5.0 to 5.5, an environment supportive of *Bifidobacterium* spp. Cow’s milk has a greater buffering capacity and is less acidic. Infants fed with cow’s milk do not have the high colonization rate by *Bifidobacterium* spp. found in breast-fed infants but have instead a colon microbiota similar to that seen in older children and adults (see [Box 2.5](#)). In areas of the body that have a low oxidation-reduction potential, the environment supports only organisms capable of fermentation, such as is seen in the gingival crevices colonized with *Bacteroides* and *Fusobacterium*.

The previously described environmental conditions may change with age, nutritional status, disease states, and drug or antimicrobial therapy use. These changes can predispose an individual to infection by the indigenous biota, a type of infection referred to as an *opportunistic infection*. For example, two groups at increased risk for gram-negative bacillus pneumonia are diabetics and alcoholics. Also, antimicrobial agents can reduce a particular population of resident bacteria, allowing the proliferation of others. An increase in age brings with it a decrease in the effectiveness of the immune response. As a result, the incidence of infection caused by opportunistic organisms increases.

Case check 2.1

The patient in the Case in Point developed diarrhea following a course of antimicrobial therapy. As described in the text, antimicrobial therapy can alter the usual biota of nearly any body site. In this case, antimicrobial therapy altered the normal bacterial biota of the gastrointestinal tract and allowed *C. difficile* to cause an infection. In this case *C. difficile* may have been a component of this patient’s bowel biota, or, more likely, the patient acquired *C. difficile* from the environment.

Composition of microbial biota at different body sites

Human microbiome studies using molecular sequencing strategies to determine which organisms reside in or on the human body have shown that the human host is colonized by many different species of microorganisms. For example, in the oral cavity alone, approximately 500 different species have been characterized. The effectiveness of the various host defenses is evidenced by the relatively low incidence of infection in immunocompetent individuals by members of the usual or indigenous microbiota. However, infections caused by members of the microbial biota are frequently encountered among immunocompromised patients. The clinical microbiologist must be able to recognize and identify the types of microorganisms found at the various body sites.

Normal microbiota of the skin

Normal skin has numerous mechanisms to prevent infection and protect the underlying tissue from invasion by potential

pathogens. These mechanisms include a physical barrier separating microorganisms from the tissues, presence of fatty acids that inhibit many microorganisms, excretion of lysozyme by sweat glands, and desquamation of the epithelium. The skin contains a wide variety of resident microorganisms, most of which are found on the most superficial layers of skin cells and the upper parts of hair follicles. Scrubbing and washing may reduce the number of bacteria present on the skin by about 90% but do not eliminate completely the organisms present, and their numbers return to normal within a few hours.

The three types of sweat glands in humans are *eccrine*, *apocrine*, and *apoecrine*. Eccrine glands are distributed abundantly in the skin and secrete mainly water and electrolytes. Apocrine glands, found mostly in the armpits and anogenital regions, produce viscous secretions. Sebaceous glands are connected to hair follicles and secrete sebum. The composition of the microbiota on the skin depends on the activity of the sebaceous or sweat glands. Organisms concentrate the most in moist areas, such as the armpit, groin, and perineum. The apocrine glands in these areas secrete substances metabolized by the skin bacteria, releasing odorous amines—the source of “body odor.” Aerobic diphtheroids are usually found in moist areas such as the axillae and between the toes. *Staphylococcus epidermidis*, *Cutibacterium* (*Propionibacterium*) *acnes*, and *Propionibacterium* spp. reside in hair follicles and metabolize products secreted by sebaceous glands. They are resistant to skin lipids and fatty acids as well as to superficial antiseptic agents commonly used to cleanse the skin.

The presence of skin bacteria benefits the host by inhibiting the growth of more pathogenic bacterial species by competing for nutrients. In addition, *S. epidermidis* and *C. acnes* secrete bacteriocins and induce the production of antimicrobial peptides by host cells, such as keratinocytes, sebocytes, and immune cells. **Bacteriocins** are peptides produced by bacteria to inhibit the growth of similar or closely related bacteria.

Microorganisms such as *C. acnes* colonize the deep sebaceous glands. Superficial antisepsis of the skin does not eliminate this organism, which may be found as a contaminant in culture specimens obtained by invasive procedures (e.g., blood, cerebrospinal fluid) because of contamination of the needle. [Box 2.1](#) lists the microorganisms most commonly found on the skin. Other organisms have been isolated from the skin but are found only occasionally or rarely and are not listed.

BOX 2.1 Microorganisms found on the skin

Common residents

Candida spp.
Cutibacterium acnes
Micrococcus spp.
Staphylococcus spp.
Propionibacterium spp.
 Diphtheroids (*Corynebacterium* spp.)

Less common or transients

Streptococcus spp.
Acinetobacter spp.
 Gram-negative rods (fermenters and nonfermenters)
Moraxella spp.

Normal microbiota of the oral cavity

The mouth contains large numbers of bacteria, with the genus *Streptococcus* predominating. Many organisms bind to the buccal mucosa and tooth surface. Unlike skin, teeth do not have a shedding epithelium. Bacteria on teeth and along the gums form a multispecies biofilm (plaque), allowing long-term colonization. Without proper oral hygiene, this can lead to dental caries and periodontitis. The bacterial plaque that develops on teeth may contain 10^{11} streptococci per gram. Plaque also results in a low oxidation-reduction potential at the tooth surface; this supports the growth of strict anaerobes, particularly in crevices and in the areas between the teeth. [Box 2.2](#) provides a partial list of microorganisms found in the oral cavity.

Normal microbiota of the respiratory tract

The respiratory tract, commonly divided into the upper and lower respiratory tract, is responsible for the delivery of air from outside of the body to the pulmonary tissues responsible for exchange of oxygen and carbon dioxide. The upper respiratory tract is composed of the mouth, nasopharynx, oropharynx, and larynx; the lower respiratory tract is composed of the trachea, bronchi, and pulmonary parenchyma. The trachea, bronchi, and lungs are protected by the action of ciliary epithelial cells and by the movement of mucus along the trachea. The tissues of these structures are normally sterile because of this protective action.

The mouth, nasopharynx, and oropharynx are colonized predominantly with viridans streptococci such as *Streptococcus mitis* group, *S. mutans* group, *S. anginosus* group, and *S. salivarius* group. *Moraxella catarrhalis*, *Neisseria* spp., and diphtheroids also colonize the upper respiratory tract. Obligate anaerobes reside in the gingival crevices, where the anaerobic environment supports these organisms. The organisms found in the mouth, nasopharynx, oropharynx, and nose, although similar, show some differences. [Box 2.3](#) lists common microorganisms encountered in the nose and

BOX 2.2 Microorganisms found in the oral cavity

Neisseria meningitidis
Streptococcus pneumoniae

nasopharynx. Attachment to host cells by streptococci and staphylococci is initially caused by hydrophobic or electrostatic interactions via bacterial surface polymers, such as pili and teichoic acids. Pili are found in the pathogenic *S. pyogenes*, *S. agalactiae*, and *S. pneumoniae* but are rare among the oral streptococci.

Opportunistic pathogens such as *S. aureus*, found in approximately 30% of healthy individuals, colonize the anterior nares. The population of the nasopharynx mirrors that of the nose, although the environment is different enough from the environment of the nose to select for several additional organisms. *Haemophilus influenzae*, *S. pneumoniae*, and *N. meningitidis*, all potential pathogens, can also be found occasionally in the nasopharynx of healthy individuals. Patients hospitalized for several days might become colonized in the upper respiratory tract by gram-negative bacteria, particularly members of the order Enterobacterales. The normal biota of the oropharynx is listed in [Box 2.4](#).

Normal microbiota of the gastrointestinal tract

The gastrointestinal tract comprises the esophagus, stomach, small intestine, and colon. The gastrointestinal tract is equipped with numerous defenses and effective antimicrobial factors. Because intestinal pathogens are usually acquired by ingestion of organisms contained in contaminated food or drink, host defenses against infections are present throughout the intestinal tract. Despite the presence of antimicrobial factors, the intestinal tract is thought to be colonized by over 35,000 bacterial species. The relation between the gut microbiota and human health is being increasingly recognized.

The microorganism population is lowest in the esophagus, about 10 microbes per gram of content. Some microorganisms colonize the esophagus, and others are present in ingested food as transient biota. The stomach contains gastric juices, acids (pH 2), and enzymes that help protect the stomach from microbial attack. Many microorganisms are susceptible to the acid pH of the stomach and are destroyed, except for the spore-forming bacterial species in their spore phase and the cysts of parasites. Even with the hostile environment of the stomach, some bacteria belonging to the genera *Streptococcus*, *Enterococcus*, and *Prevotella* as well as the opportunistic pathogen *Helicobacter pylori* can inhabit the stomach. These organisms associate themselves with the stomach lining,

protected by the layer of mucus that lines the stomach. Organisms that are pH-susceptible and survive are generally protected by being enmeshed in food as they move to the small intestine. The stomach acidity reduces the number of viable organisms that reach the small intestine.

The small intestine contains fewer microorganisms compared with those usually present in the colon. Microorganisms prevalent in the colon may produce a count of 10^{12} bacteria per gram of solid material. In fact, the colon contains over 70% of all microbes found in the body. Obligate anaerobes, such as *Bacteroides*, *Bifidobacterium*, *Clostridium*, *Prevotella*, and *Porphyromonas*, far outnumber the facultative gram-negative bacilli, making up more than 90% of the microbial biota of the large intestine. Gram-positive cocci belonging to the genera *Streptococcus* and *Enterococcus* and yeasts are also present in the large intestine. A single-layer epithelium, renewed every 5 days, lines the intestine. The tight junction spaces between epithelial cells make it difficult for bacteria to penetrate the epithelium. Many of the bacteria colonizing the intestines do so using pili.

The gastrointestinal tract population may be altered by antimicrobial agents. In some cases, certain populations or organisms are eradicated or suppressed, and other members of the indigenous biota can proliferate. For example, *C. difficile* or the yeast *Candida albicans* can flourish in the intestinal tract of some people who are taking an oral broad-spectrum antimicrobial agent. This alteration can be the cause of a severe necrotizing enterocolitis (*C. difficile*), diarrhea (*C. albicans*, *S. aureus*), or other superinfection. The bacteria constituting the usual intestinal biota also carry out various metabolic degradations and nutrient production that appear to play a role in the health of the host. The organisms found in the gastrointestinal tract are summarized in [Box 2.5](#).

Normal microbiota of the genitourinary tract

The kidneys, bladder, cervix, and fallopian tubes are normally sterile, although a few organisms originating from the perineum can be found in the distal urethra, particularly in women.

Prevotella spp.
Streptococcus spp.

Case check 2.2

In the Case in Point, antimicrobial therapy led to an alteration of the patient's normal gastrointestinal tract biota. As shown in [Box 2.5](#), *Clostridium* spp. and *C. difficile* can be part of the normal gastrointestinal tract microbiota in humans. In this case, eliminating some of the bacterial gut biota allowed *C. difficile* organisms to grow unchecked and cause an infection called *C. difficile*–associated disease that is often associated with prolonged antimicrobial therapy, as discussed in [Chapter 22](#).

The urethra is colonized in its outermost segment by organisms found on the skin. The composition of the vaginal microbiota is consistent with hormonal changes and age. Before puberty and in postmenopausal women, vaginal biota primarily consists of yeasts, gram-negative bacilli, and gram-positive cocci. During childbearing years, high estrogen levels promote the deposition of glycogen in vaginal epithelial cells. Lactobacilli metabolize glycogen from vaginal epithelial cells to maintain a low pH, creating an environment that is inhibitory to many organisms. However, the low pH encourages colonization of the vagina with lactobacilli, anaerobic gram-negative bacilli, and gram-positive cocci. Microorganisms usually isolated from the genitourinary tract are listed in [Box 2.6](#).

Role of the microbial biota in the pathogenesis of infectious disease

Some organisms that make up the microbial biota live off the host's nutrients, but in most cases, they provide some benefit to the host, creating a symbiotic relationship with the host, as mentioned earlier. However, certain members of the normal microbiota are **opportunists**; they cause disease when their habitat is altered or when the host's immune system is compromised. In the case of trauma, either accidental or surgical, enough of the normal microbiota found in the traumatized area may reach sterile or other areas in the body where these organisms are not part of the microbial biota. For example, patients who undergo surgery become susceptible to infections caused by organisms that colonize the surgical site (e.g., abdominal cavity); leakage following perforation of the colon spills the contents of the colon into the peritoneal cavity, leading to an infection by the colon biota.

The host's immune response may be reduced or altered because of suppression by immunosuppressive drugs, chemotherapy, or radiation. Individuals with lymphoma, leukemia, or other blood disorders in which there is a functional defect in phagocytic activity or a decrease in the number of functioning cells or in which chemotactic activity is impaired also may have a reduced immune response. Members of the microbial biota also may initiate an infection or make an infection more serious in patients with chronic illnesses, including diabetes or severe hepatic disease such as cirrhosis.

Role of the microbial biota in the host defense against infectious disease

The microbial biota provide beneficial effects, and the development of immunologic competence depends on this biota. Vitamins and other essential nutrients are synthesized by certain bacteria in the intestine and appear to contribute to the overall health of the host.

The immune system is constantly primed by contact with microorganisms. In the gut, normal microbiota interact with host Toll-like receptors (TLRs), such as TLR5 found on epithelial cells and dendritic cells. Activation of TLR5 recruits T and B lymphocytes (T and B cells), leading to the production of immunoglobulin A (IgA) to limit the overcolonization of gut microbiota. Animals born and raised in a germ-free environment have a poorly functioning immune system. Exposure to otherwise innocuous organisms can be fatal to such animals. Likewise, consider how a sterile environment might affect a newborn. Antibody production would not be stimulated, and the mononuclear phagocyte system would remain undeveloped. Serum immunoglobulin G (IgG) and other antibodies effective against microorganisms would be suppressed, which would make the individual more susceptible to pathogenic microorganisms. Without activation by microorganisms and the supporting action of antigen-presenting cells and cytokines, cell-mediated immunity would not develop normally.

The microbial biota produce conditions at the microenvironmental level that block colonization by extraneous pathogens (e.g., competition for nutrients and secretion of bacteriocins). These proteins are produced by a variety of

gram-positive and gram-negative bacteria and appear to give the secreting bacterium an advantage because they can eliminate other bacteria that would compete for nutrients and space. Some species of bacteria produce metabolic by-products that result in a microenvironment that is hostile to potential pathogens.

When the composition of the indigenous biota is altered (e.g., by broad-spectrum antimicrobial therapy), other organisms capable of causing disease may fill the void. For example, gastroenteritis caused by *Salmonella* is generally not treated with antimicrobial agents and is better eliminated by natural exclusion by the colon biota. If the microbial biota are eliminated, such as in patients receiving antimicrobial therapy, resistant or more pathogenic species may be able to establish infection. For example, the yeast *C. albicans* can multiply and cause diarrhea or infections in the mouth or vagina when the normal biota have been eliminated.

The microbial biota play an important role in both health and disease. Although reduction of the usual biota can have profound negative effects, many common infections are caused by members of the resident biota. Knowledge of the role of these organisms in the pathogenesis of an infectious disease is helpful in assessing their significance when they are isolated from clinical samples.

Microbial factors contributing to pathogenesis and virulence

Pathogenesis

Pathogenicity is the ability of a microbe to produce disease in an individual. An organism may be described as a *true pathogen* or an *opportunistic pathogen*. True pathogens are organisms recognized to cause disease in healthy immunocompetent individuals a high percentage of the time. Bacterial species such as *Yersinia pestis* and *Bacillus anthracis* are pathogenic in nearly all situations; when these species are recovered in clinical samples, they are clinically significant.

Today, individuals with disease are living longer and are more likely to undergo invasive medical procedures, organ transplantation, and insertion of prosthetic devices, making them more susceptible to infections. As a result, organisms of the normal biota are being seen with increasing frequency in those patients and individuals who are immunosuppressed. *H. influenzae* colonizes the upper respiratory tract of healthy individuals without causing disease, but given the opportunity, it can rapidly produce a life-threatening infection involving the lower respiratory tract. Organisms such as *S. epidermidis* do not cause disease under usual conditions but can induce an infectious process in patients with prosthetic devices. *H. influenzae* and *S. epidermidis* are called *opportunistic pathogens*, and the infections they cause are called *opportunistic infections*. Table 2.1 lists common opportunistic microorganisms and the conditions with which they are commonly associated.

Because of compromised hosts, our definition of *pathogen* must be expanded to apply to virtually any microorganism when conditions for infection are met. In deciding whether a particular organism that has been isolated is a pathogen, we also must consider the human host from whom the organism was isolated and whether that host has underlying disease

Table 2.1 Abbreviated list of opportunistic microorganisms

Conditions compromising host defenses	Organism(s)
Foreign bodies (catheters, shunts, prosthetic heart valves)	<i>Staphylococcus epidermidis</i> <i>Cutibacterium acnes</i> Viridans streptococci <i>Serratia marcescens</i> <i>Pseudomonas aeruginosa</i> <i>Aspergillus</i> spp. <i>Candida albicans</i>
Alcoholism	<i>Streptococcus pneumoniae</i> <i>Klebsiella pneumoniae</i>
Burns	<i>Pseudomonas aeruginosa</i> <i>Acinetobacter baumannii-calcoaceticus</i> complex <i>Staphylococcus aureus</i>
Hematoproliferative disorders	<i>Cryptococcus neoformans</i> Varicella-zoster virus
Cystic fibrosis	<i>Pseudomonas aeruginosa</i> <i>Burkholderia cepacia</i>
Immunosuppression (drugs, congenital disease)	<i>Aspergillus</i> spp. <i>Candida albicans</i> <i>Pneumocystis jirovecii</i> Diphtheroids (<i>Corynebacterium</i> spp.) <i>Pseudomonas</i> spp. <i>Staphylococcus</i> spp. Cytomegalovirus Herpes simplex virus Varicella-zoster virus

that may increase susceptibility to infection. For example, the potential pathogen list for a healthy 20-year-old individual is much shorter than that for a healthy 90-year-old individual, a transplant recipient, or a 20-year-old individual with acquired immunodeficiency syndrome (AIDS). Almost any organism in the right place can cause an infection, and this must be considered when performing invasive procedures because an inadvertent result of intervention can be the transfer of an organism from where it is present as part of the indigenous biota to a place where it can replicate and cause infection. Contamination by resident skin biota of a surgical incision can lead to a serious wound infection.

An **iatrogenic infection** is an infection that occurs as the result of medical treatment or procedures. For example, many patients who have indwelling urinary catheters develop a urinary tract infection. Although placement of the catheter was a necessary procedure in the medical treatment of the individual, its use may result in an infection. Patients who are given immunosuppressive drugs because they have received an organ transplant are more susceptible to infection. Because any infection in such a patient would probably be the result of the physician-ordered drug therapy, it would be considered an iatrogenic infection.

Routes of transmission

The first step in initiating an infection is for the infectious agent to gain access to the host. The route by which a pathogen can be transmitted to a susceptible host is an important factor in the establishment of infection. The agent must be able to evade host defenses and colonize the tissue at the point of entry. Although some organisms may be naturally transmitted by more than one route, most have a preferred portal of entry. These routes can be characterized as through air (inhalation), via food and water (ingestion), through close contact (includes sexual transmission), through cuts and bites, and via arthropods; animal diseases that can infect humans are transmitted through animal contact (**zoonoses**). The routes of transmission are summarized in [Table 2.2](#). [Fig. 2.1](#) shows the routes of entry to and exit of microbes from the body.

Airborne transmission

Respiratory spread of infectious disease is common and is generally an efficient way to enter a host. Often, the respiratory secretions from an infected host are aerosolized by coughing, sneezing, and talking. Very small particles, referred to as *aerosols*, are the residue from the evaporation of fluid from larger droplets and are light enough to remain airborne for long periods. Large respiratory droplets fall to the ground before they evaporate contaminating surfaces. This results in droplet-contact spread in which disease transmission occurs because of touching the contaminated surface.

Pathogens that are spread through the air generally must be resistant to drying and inactivation by ultraviolet light. Some infectious agents may be transmitted by dust particles that have become airborne. As discussed earlier in this chapter, the body has many defenses against airborne infectious agents. The nasal turbinates, oropharynx, and larynx provide a twisting, mucus-lined passageway that makes direct access to the lower respiratory tract mechanically difficult. In addition, the lower portions of the respiratory tract contain ciliary epithelium that sweeps organisms upward. For a microorganism to cause disease, it must circumvent these defenses, penetrate the mucous layer, and attach to the epithelium. The host also produces secretory IgA, lysozyme, alveolar macrophages, and other factors that act on the pathogen that manages to get beyond the physical barriers.

Respiratory tract infections are the most common reason that patients of all ages seek medical attention. Although most upper respiratory tract infections are self-limiting and can be treated with over-the-counter medications, some are more serious. Streptococcal sore throat, sinusitis, otitis media, acute epiglottitis, and diphtheria can be serious and even life-threatening. Viral diseases causing the common cold and infectious mononucleosis are usually not life-threatening but can result in much discomfort and absenteeism from work or school.

Although all of the diseases mentioned can be spread via aerosols, some may also be transmitted via the fingers and hands; this is especially true of the common cold-causing rhinoviruses. The fingers and hands are contaminated with infectious nasal secretions because of hand-to-nose contact. The infectious viral particles are passed from the infected individual to a susceptible recipient via hand-to-hand or hand-to-face contact. The recipient transmits the virus picked up from

the infected individual by touching the face and nose. In this case, the disease is transmitted via the respiratory route but not in the normal, classic manner of respiratory transmission.

Transmission may also result from contact with inanimate objects contaminated with the infectious agent (**fomites**). For example, a doorknob is contaminated by the hand and fingers of an infected individual, and the virus is transmitted to a susceptible person's hand and fingers when that person opens the door. Control of such transmission is often as simple as frequent handwashing.

Infections of the lower respiratory tract are less common but more serious than infections of the upper respiratory tract. The organisms causing these infections have managed to bypass host defenses, or the host defenses have been compromised (e.g., by alcoholism, heavy smoking), allowing the pathogen access to the normally sterile, deeper portions of the respiratory tract.

The most common microorganism causing lower respiratory tract infection in individuals older than 30 years of age is *S. pneumoniae*. Risk increases with age. Although the pneumococcus is the most common cause of community-acquired pneumonia, it is also often seen in aspiration pneumonia, a common type of hospital-acquired pneumonia. Pneumococcal pneumonia begins suddenly and is a serious, life-threatening disease, particularly in older patients. The bacteria produce a large capsule that resists phagocytosis. In chronic lower respiratory tract infections, the survival of the infecting agent within phagocytes plays a role in the pathogenic mechanism. As the agent of tuberculosis, a chronic debilitating infection, *M. tuberculosis* is the classic example of an intracellular pathogen. This organism is highly virulent, is invasive, survives well, and multiplies within phagocytes. Infections are often chronic and result in granuloma formation.

Transmission by food and water

Transmission of gastrointestinal infections is usually a result of ingestion of contaminated food or water. In some situations, infection occurs via the fecal-oral route. The digestive tract is colonized with vast numbers of different microorganisms. Under usual conditions, the gut biota maintain a harmless relationship with the host. Gastric enzymes and acids in the stomach prevent survival of most organisms, but many survive and colonize the small intestine and colon.

Gastrointestinal infections result from organisms that survive the harsh conditions of the stomach and competition with the microbial biota and then produce damage to the tissues of the gastrointestinal tract. This damage is a result of either ingestion of a preformed toxin or disruption of the normal functioning of the intestinal cells by invasion of the pathogen or production of a toxin within the intestine.

Organisms that can cause disease by means of a preformed toxin, produced outside the body, include *Clostridium botulinum*, *Bacillus cereus*, and *S. aureus*. The severity of disease ranges from mild diarrhea to rapidly fatal intoxication. Food poisoning by *B. cereus* and *S. aureus* is relatively common and is self-limiting. Botulism, caused by *C. botulinum*, although rare, can be life-threatening.

Other bacteria produce a toxin after infecting the intestinal tract. Generally, to be effective as a pathogen, an organism must survive, adhere to, and colonize the intestinal mucosa and either produce a toxin or invade deeper tissues. A commonly seen cause of diarrhea and intestinal infection is

Table 2.2 Common routes of transmission^a

Route of exit	Route of transmission	Example
Respiratory	Aerosol inhalation	Influenza virus, tuberculosis, <i>Neisseria meningitidis</i>
	Nose or mouth (droplets) → hand or object → nose	Common cold (rhinovirus)
Salivary	Direct salivary transfer (e.g., kissing)	Oral-labial herpes; infectious mononucleosis
Gastrointestinal	Stool → hand → mouth and/or stool → object → mouth	Enteroviruses; hepatitis A
	Stool → water or food → mouth	Salmonellosis; shigellosis
Skin	Skin discharge → air → respiratory tract	Varicella; poxvirus infection
	Skin to skin	Human papillomavirus (warts); syphilis
Blood	Transfusion or needle prick	Hepatitis B; cytomegalovirus infection; malaria; HIV
	Insect bite	Malaria; relapsing fever; West Nile virus
Genital secretions	Urethral or cervical secretions	Gonorrhea; herpes simplex; <i>Chlamydia</i> infection
	Semen	Cytomegalovirus infection
Urine	Urine → hand → catheter	Hospital-acquired urinary tract infection
	Urine → aerosol (rare)	Tuberculosis
Eye	Conjunctival	Adenovirus
Zoonotic	Animal bite	Rabies, <i>Pasteurella multocida</i>
	Contact with carcasses	Tularemia
	Arthropod	Lyme disease, Rocky Mountain spotted fever, plague

^aThe examples cited are incomplete, and in some cases more than one route of transmission exists.

HIV, Human immunodeficiency virus.

Fig. 2.1 Routes of entry and exit. (Reprinted from Mims, C.A., et al. (2001). *Mims' pathogenesis of infectious disease* [5th ed.]. San Diego: Elsevier Ltd. With permission from Elsevier.)

Escherichia coli. This organism is a member of the intestinal resident biota; however, some strains of *E. coli* produce virulence factors that cause alterations in the biochemical activity of the intestinal epithelial cells, resulting in problems with fluid and electrolyte control by the intestinal cells. These strains of *E. coli*, referred to as *diarrheagenic*, are a common cause of traveler's diarrhea and other intestinal problems. *Vibrio cholerae*, the cause of cholera, produces an enterotoxin that causes an outpouring of fluid from the cells into the lumen of the intestine. Massive amounts (20L per day) of fluid can be lost. Other intestinal pathogens include *C. difficile* (see Case in Point), *Shigella* spp., *Aeromonas hydrophila*, *Campylobacter jejuni*, and *Salmonella* spp. The infective dose, severity, and incidence of disease vary with the agent.

Numerous viruses also cause diarrheal disease. They multiply within the cells of the intestinal mucosa and affect the normal function of the cells. Viral agents in this category include rotavirus, adenovirus, coxsackievirus, and *Norovirus* spp. The incidence of diarrhea caused by these agents is high, especially when people are in close contact (e.g., in daycare centers, nursing homes, military camps, cruise ships). Some viruses enter via the gastrointestinal tract and infect the liver, such as hepatitis A and E viruses. Numerous parasites, such as *Cryptosporidium* spp., *Giardia lamblia*, *E. histolytica*, and *Balantidium coli*, also infect the gastrointestinal tract.

Close contact

Typically, the routes of transmission of infectious diseases require close contact. For a respiratory pathogen to be transmitted via aerosols, the susceptible host must be relatively close. However, aerosolized pathogens can stay airborne for some time and be carried by gentle air currents. For this discussion, *close contact* refers to passage of organisms by salivary, skin, and genital contact. Two prominent infections passed by direct transfer of saliva (e.g., kissing) are herpes simplex virus and Epstein-Barr virus. Skin-to-skin transfer of infectious disease is not as common as for some of the other routes, but diseases such as warts (human papillomavirus), syphilis, and impetigo result when material from infectious lesions inoculates the skin of a susceptible host. The list of sexually transmitted diseases is a long one. In North America, the most commonly transmitted venereal agents are human papillomavirus, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, herpes simplex virus, *Treponema pallidum* subsp. *pallidum* (syphilis), *Trichomonas* spp., and human immunodeficiency virus (HIV).

Cuts and bites

The classic example of a bite-wound infection is rabies. However, human rabies is relatively rare. Of more concern with animal bites, and especially human bites, is infection by the mouth biota. Dog-bite and cat-bite infections often yield *Pasteurella multocida*, but the possibilities are extensive. Human bites are dangerous because the human oral biota comprises many different organisms in extremely high numbers, including obligate anaerobic bacteria.

Arthropods

Infectious agents can enlist the help of arthropods for transmission among hosts. Infection following a mosquito, tick,

flea, or mite bite is a common occurrence in many parts of the world. Diseases spread by arthropods include malaria, relapsing fever, plague, Rocky Mountain spotted fever, Lyme disease, West Nile fever, and untold numbers of regional viral hemorrhagic fevers. In most cases, the infectious agent multiplies in the arthropod, which then transmits the agent while feeding on a human host. This mode of transmission is much more common in the tropics because arthropods are active year-round. However, a significant number of **arthropod-borne** diseases occur in temperate zones.

Zoonoses

The route of transmission known as *zoonosis* depends on contact with animals or animal products. Certain organisms causing disease in animals may also infect humans who have contact with them. These diseases may be passed by animal bites (rabies), arthropod vectors (plague), contact with secretions (brucellosis), and contact with animal carcasses and products (tularemia, listeriosis). The diseases are transmitted by the routes already discussed. The common factor is that, regardless of the route, the disease is a disease of animals that is transmitted to humans. A partial list of zoonotic diseases and infecting organisms is provided in [Table 2.3](#).

Table 2.3 Zoonoses

Disease	Organism
Anthrax	<i>Bacillus anthracis</i>
Brucellosis	<i>Brucella</i> spp.
Erysipeloid	<i>Erysipelothrix rhusiopathiae</i>
Leptospirosis	<i>Leptospira interrogans</i>
Tularemia	<i>Francisella tularensis</i>
Ringworm	<i>Trichophyton</i> spp. <i>Microsporum</i> spp.
Lyme disease	<i>Borrelia burgdorferi</i>
Plague	<i>Yersinia pestis</i>
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>
Yellow fever	Flavivirus
Encephalitis	Alphavirus
Rabies	Rhabdovirus
Blastomycosis	<i>Blastomyces dermatitidis</i>
Tuberculosis	<i>Mycobacterium bovis</i>
Q fever	<i>Coxiella burnetii</i>
Ornithosis	<i>Chlamydophila psittaci</i>
Gastroenteritis	<i>Campylobacter</i> spp. <i>Salmonella</i> spp.
Listeriosis	<i>Listeria monocytogenes</i>
Giardiasis	<i>Giardia lamblia</i>
Toxoplasmosis	<i>Toxoplasma gondii</i>
Tapeworms	<i>Taenia saginata</i> <i>Taenia solium</i> <i>Diphyllbothrium latum</i> <i>Echinococcus</i> spp.
Trichinosis	<i>Trichinella spiralis</i>

Virulence

Virulence is the relative ability of a microorganism to cause disease or the degree of pathogenicity. It is usually measured by the numbers of microorganisms necessary to cause infection in the host. Organisms that can establish infection with a relatively low infective dose are considered more virulent than organisms that require high numbers for infection. For example, because *Shigella* spp. cause disease with a relatively low infective dose (100 organisms), *Shigella* is considered a highly virulent organism. This generalization is misleading because the severity of disease caused by different organisms varies from one to another. If a microorganism requires a relatively high infective dose but the disease it causes is often fatal, we tend to think of the microorganism as highly virulent. A different organism may require a low infective dose but produce a relatively mild disease.

Microbial virulence factors

Infectious organisms have a wide variety of mechanisms or virulence factors that allow them to persist in a host and cause disease. Some virulence factors, such as capsules and toxins, are used by many organisms. Other virulence factors tend to be specialized and specific to one particular organism, such as the tissue tropism of *N. gonorrhoeae*. Virulence factors allow the pathogen to evade or overcome host defenses and cause disease, and they encompass functions such as facilitating adhesion to host cells or tissues, inhibiting phagocytosis, enhancing intracellular survival after phagocytosis, and damaging tissue through the production of toxins and extracellular enzymes. Many virulence factors are well defined, such as the diphtheria and cholera toxins, the capsule of *S. pneumoniae*, and the fimbriae of *N. gonorrhoeae*. Certain microorganisms produce extracellular factors that appear to aid in infection, but the exact role of these factors is unknown.

Ability to resist phagocytosis

Phagocytes, or phagocytic cells, such as macrophages and polymorphonuclear cells, play a major role in defending the host from microbial invasion. These cells ingest bacteria and destroy them. The lack of functioning phagocytic cells leaves the host susceptible to overwhelming infection. Therefore an extremely important event in the life of an invading pathogen is avoiding phagocytosis. There are many ways by which microbial species evade phagocytosis; some are listed in [Table 2.4](#).

The most common mechanism for evading phagocytosis used by microorganisms is a polysaccharide capsule. Many microorganisms possessing a capsule are highly virulent until removal of the capsule, at which point virulence becomes extremely low. Encapsulated strains of *S. pneumoniae* and *H. influenzae* are associated with highly invasive infections and are known to be more virulent than non-encapsulated strains. Host antibodies directed against the capsule can enhance phagocytosis and also decrease the microbe's virulence, a process called *opsonization*. The capsule is usually composed of polysaccharides but can also be made of proteins or a combination of proteins and carbohydrates. The capsule inhibits phagocytosis primarily by masking the cell surface structures that are recognized by receptors on the surface of the

phagocytic cell and in the same manner inhibits activation of complement by masking structures to which complement proteins bind.

Another bacterial structure that protects organisms from phagocytosis is protein A. Protein A in the cell wall of *S. aureus* helps the organism avoid phagocytosis by interfering with the binding of the host's antibodies to the surface of the organism. Antibodies bind to antigens via their fragment antigen-binding (Fab) portion. Protein A binds to the Fc (crystalline fragment) portion of IgG (at the opposite end of the Fab sites), preventing opsonization and phagocytosis by turning the antibody around on the surface.

Some organisms evade phagocytic cell killing by releasing toxins in tissues that kill phagocytes. Streptococci produce hemolysins that lyse red blood cells and induce toxic effects on white blood cells and macrophages. Pathogenic staphylococci release **leukocidins** that cause lysosomal discharge of white blood cells into the cytoplasm. A staphylococcal leukocidin, called *Panton-Valentine leukocidin*, is lethal to leukocytes and may contribute to the invasiveness of the organism. Other organisms inhibit chemotaxis, which is the movement of white blood cells to sites of tissue damage, and the host is less able to direct polymorphonuclear neutrophils (PMNs) and macrophages into the site of infection.

Structures that promote adhesion to host cells and tissues

Most infectious agents must attach to host cells before infection occurs. In intoxication diseases caused by exotoxins (e.g., botulism, staphylococcal food poisoning), microbial adherence is not important. However, in virtually all other cases, the bacterium, virus, or fungus requires adherence to host cells before infection and disease can progress. Without adhering to host cells, the pathogen can be carried away in fluid (e.g., urine or mucus). The microbial or viral surface structures that mediate attachment are called **adhesins**. Host cells must possess the necessary **receptors** for the adhesins, generally a carbohydrate. If the host or the infectious agent undergoes a mutation that changes the structure of the adhesin or the host receptor, adherence can be less efficient or not take place, and the virulence of the infectious agent is affected. [Fig. 2.2](#) illustrates surface bacterial structures that are involved in the pathogenesis of disease.

The main adhesins in bacteria are surface proteins and polysaccharides. Extending from the surface of many human bacterial pathogens are **fimbriae (pili)**. On the tips of fimbriae are adhesion proteins that bind to receptors on cell surfaces. Fimbriae enable bacteria to adhere to host cell surfaces, increasing the organism's colonizing ability and providing resistance to phagocytosis. Once bacteria are attached to nonphagocytic cells, phagocytosis by white blood cells is less likely to occur. For example, the strains of *E. coli* that cause traveler's diarrhea use their fimbriae to adhere to cells of the small intestine, where they secrete a toxin that causes the disease symptoms. Similarly, fimbriae are essential for *N. gonorrhoeae* to infect the epithelial cells of the genitourinary tract. Antibodies to the fimbriae of *N. gonorrhoeae* are protective by preventing the organism from attaching to the epithelial cells. Similarly, antibodies to viral adhesions prevent infection.

Table 2.4 Microbial interference with phagocytic activities

Microorganisms ^a	Type of interference ^b	Mechanism (or responsible factor)
<i>Streptococcus pyogenes</i>	Kill phagocyte Inhibit neutrophil chemotaxis Resist phagocytosis	Streptolysin induces lysosomal discharge into cell cytoplasm Streptolysin M and M-like proteins Hyaluronic acid capsule
<i>Staphylococcus aureus</i>	Kill phagocyte Inhibit opsonized phagocytosis Resist killing Block chemotaxis	Leucocidin induces lysosomal discharge into cell cytoplasm SpA binds Fc portion of Ab Polysaccharide capsule in some strains
<i>Bacillus anthracis</i>	Kill phagocyte Resist killing	Lethal factor of tripartite toxin Capsular polyglutamic acid
<i>Haemophilus influenzae</i>	Resist phagocytosis (unless Ab present)	Polysaccharide capsule
<i>Streptococcus pneumoniae</i>	Resist phagocytosis (unless Ab present)	Polysaccharide capsule
<i>Klebsiella pneumoniae</i>	Resist phagocytosis	Polysaccharide capsule
<i>Pseudomonas aeruginosa</i>	Kill phagocyte Resist phagocytosis	Exotoxin A kills macrophages; also four type III toxins: exoenzyme (Exo) Alginate exopolysaccharide
<i>Escherichia coli</i>	Resist phagocytosis (unless Ab present) Kill macrophages	O antigen (smooth strains) K antigen (acid polysaccharide)
<i>Salmonella</i> spp.	Resist phagocytosis (unless Ab present) Resist killing; survival in macrophages Kill phagocyte	Vi antigen Secreted products of SPI-2 Secreted products of SPI-1
<i>Clostridium perfringens</i>	Inhibit chemotaxis Resist phagocytosis	α -toxin Capsule
<i>Cryptococcus neoformans</i>	Resist phagocytosis	Capsular polyuronic acid
<i>Yersinia pestis</i>	Kill phagocyte	Yersinia outer protein (Yop)
<i>Mycobacteria</i>	Resist killing Digestion Inhibit lysosomal fusion	Cell wall substance
<i>Brucella abortus</i>	Resist killing	Cell wall substance
<i>Toxoplasma gondii</i>	Inhibit attachment to neutrophil Inhibit lysosomal fusion	

Ab, Antibody; SpA, staphylococcal protein A; SPI-1, *Salmonella* pathogenicity island 1; SPI-2, *Salmonella* pathogenicity island 2; Yop, *Yersinia* outer protein.

^aOften only the virulent strains show the type of interference listed.

^bSometimes the type of interference listed has been described only in a particular type of phagocyte (polymorph or macrophage) from a particular host, but it generally bears a relationship to pathogenicity in that host.

Modified from Mims, C. A. (2015). *The pathogenesis of infectious disease* (6th ed.). New York: Academic Press.

Fig. 2.2 Surface bacterial structures that are involved in the pathogenesis of disease. (From Kumar, V, et al. (2005). *Robbins and Cotran pathologic basis of disease* [7th ed.]. Philadelphia: Saunders.)

Some human pathogens express adhesion proteins not associated with fimbriae. When encountering host tissue, several gram-positive bacteria, like *S. aureus*, use molecular adhesion molecules that include teichoic acid, lipoteichoic acid, and lipoproteins. The primary tissue receptor is TLR2 found on epithelial cells, endothelial cells, and leukocytes. However, binding to TLR2 on keratinocytes leads to the release of antimicrobial peptides and proinflammatory cytokines and neutrophil-attracting chemokines, an integral part of our innate defense mechanism. An additional adherence mechanism used by bacteria is a biofilm. Some bacteria secrete a sticky polysaccharide that binds bacterial cells together and to host cells or nonliving surfaces. Biofilms, discussed in [Chapter 31](#), can also protect bacteria from phagocytosis and antibodies.

Ability to survive intracellularly and proliferate

Bacteria are engulfed by some host cells, such as macrophages, into a cytoplasmic vacuole called a *phagosome*. Phagosomes fuse with lysosomes producing phagolysosomes, resulting in microbial killing. Lysosomes contain several antimicrobial factors. The process of phagocytosis is discussed in more detail later in this chapter. After phagocytosis, some pathogens survive within the phagocytic cell. Microorganisms have developed several methods to prevent being killed intracellularly. Some organisms prevent fusion of phagosomes and lysosomes, others escape from the phagosome into the cytoplasm, and still others are resistant to the effects of the lysosomal contents.

Bacteria that prevent phagolysosomal formation can survive and multiply inside the macrophage. Bacterial species, such as *Chlamydia*, *Mycobacterium*, *Brucella*, and *Listeria* species, are easily engulfed by macrophages and phagocytes. However, these species are not only able to grow inside the macrophages, but they are protected from the host's other immune defenses and are called *intracellular parasites*. The bacterium *Coxiella burnetii* can grow inside the harsh environment of a phagolysosome.

To establish itself and cause disease, a pathogen must be able to replicate after attachment to host cells. Numerous host factors work to prevent proliferation: secretory antibody acts as an opsonin, enhancing phagocytosis; **lactoferrin** binds iron (an essential trace element); and **lysozyme** lyses bacteria. To be successful in establishing infection, infectious agents must be able to avoid or overcome these local factors. Lactoferrin competes with bacteria for free iron; *N. meningitidis* can use lactoferrin as a source of iron and is therefore not inhibited by its presence. The nonpathogenic *Neisseria* spp. are usually unable to use the iron in lactoferrin and are inhibited by its presence.

Several pathogens (*H. influenzae*, *N. gonorrhoeae*, and *N. meningitidis*) produce an IgA protease that degrades IgA found at mucosal surfaces. Other pathogens (influenza virus, *Borrelia* spp.) circumvent host antibodies by changing key surface antigens. The host produces antibodies against the "old" antigens, which are no longer effective because the agent now has "new" antigens that do not bind to antibodies made against the old antigens.

Pathogens exhibit an ability to penetrate and grow in tissues, a process called *invasion*. With some organisms, the invasion is localized and involves only a few layers of cells. For example, *N. gonorrhoeae* attaches to cells in the genital

area, penetrates into the cells, and multiplies. The bacteria pass through the cells into the subepithelial space and establish an infection. With some organisms, such as *Salmonella* spp., the organisms spread to distant sites (organs and tissues), often via the bloodstream. This is called **dissemination**. Other organisms, such as *Corynebacterium diphtheriae*, do not spread beyond their initial site of infection, yet the disease they produce is serious and often fatal because the exotoxins they produce are disseminated. Certain organisms that survive phagocytosis can be disseminated rapidly to many body sites, but the organisms themselves are not invasive. The phagocyte carries the organism to other body sites, but the bacterium itself is incapable of penetrating tissues.

Ability to produce extracellular toxins and enzymes

Generally, disease from infection is noticeable only if tissue damage occurs. This damage may be from toxins, either **exotoxins** or **endotoxins**, or from inflammatory substances that cause host-driven, immunologically mediated damage. The ability of organisms to produce exotoxins and extracellular enzymes is another major factor that contributes to the virulence and invasiveness of organisms. Toxins are poisonous substances produced by organisms that interact with host cells, disrupting normal metabolism and causing harm. Exotoxins are produced by both gram-negative and gram-positive bacteria and are secreted by the organism into the extracellular environment, or they are released on lysis of the organism.

Exotoxins can mediate direct spread of the microorganisms through the matrix of connective tissues and can cause cell and tissue damage. Some organisms produce soluble substances, such as proteases and hyaluronidases that liquefy the hyaluronic acid of the connective tissue matrix, helping bacteria to spread in tissues, promoting the dissemination of infection.

Endotoxins are a constituent, the lipopolysaccharide (LPS), of the outer cell membrane of gram-negative bacteria exclusively. Endotoxins, in contrast with exotoxins, do not have enzyme activity, are secreted in only very small amounts, do not have specificity in their activity on host cells, are generally not very potent, and are not destroyed by heating. Endotoxins are released in large amounts when the bacterial cell lyses.

Exotoxins

Most bacterial exotoxins are composed of two subunits: one is nontoxic and binds the toxin to the host cells and the other has toxic activity. The toxin gene is commonly encoded by phages, plasmids, or transposons. Only the organisms that carry the DNA coding for the toxin gene produce toxin. Isolates of *C. difficile*, for example, must be tested for the presence of toxin genes, such as in the Case in Point. Diphtheria toxin inhibits protein synthesis and affects the heart, nerve tissue, and liver. Botulinum toxin is a neurotoxin that blocks nerve impulse transmission, causing flaccid paralysis, especially in infants. *S. pyogenes* and *S. aureus* both produce exfoliatin, which causes a rash and massive skin peeling or exfoliation. [Table 2.5](#) lists many bacterial exotoxins that are important in disease.

Table 2.5 Examples of exotoxins of pathogenic bacteria

Bacterium	Disease caused in humans	Toxins
<i>Bacillus anthracis</i>	Anthrax	Lethal, edema-producing toxins
<i>Bordetella pertussis</i>	Whooping cough (pertussis)	Lethal, necrotizing toxin
<i>Clostridium botulinum</i>	Botulism	Six type-specific lethal neurotoxins ^a
<i>Clostridioides difficile</i>	Antibiotic-associated diarrhea, pseudomembranous colitis	Toxin A, enterotoxin ^a Toxin B, cytotoxin ^a
<i>Clostridium novyi</i>	Gas gangrene	Alpha, lethal, necrotizing Beta, lethal, necrotizing, hemolytic Gamma, lethal, necrotizing, hemolytic Delta, hemolytic Epsilon, lethal, hemolytic Zeta, hemolytic
<i>Clostridium perfringens</i>	Gas gangrene, food poisoning, enteritis necroticans	Alpha, lethal, necrotizing, hemolytic ^a Beta, lethal, necrotizing Gamma, lethal, necrotizing, hemolytic Delta, lethal Epsilon, lethal, necrotizing Iota, lethal, necrotizing Theta, lethal, cardiotoxic, hemolytic Kappa, lethal, proteolytic Enterotoxin ^a
<i>Clostridium septicum</i>	Gas gangrene	Alpha, lethal, hemolytic, necrotizing
<i>Clostridium sordellii</i>	Gas gangrene	Lethal toxin ^a Hemorrhagic toxin ^a
<i>Clostridium tetani</i>	Tetanus	Tetanospasmin, lethal, neurotoxic ^a Neurotoxin, nonspasmogenic Tetanolysin, lethal, cardiotoxic, hemolytic
<i>Corynebacterium diphtheriae</i>	Diphtheria	Diphtheria toxin, lethal, necrotizing ^a
<i>Escherichia coli</i> (unique strains)	Diarrhea	Heat-labile enterotoxin ^a Heat-stable enterotoxin Shiga toxin
<i>Pseudomonas aeruginosa</i>	Pyogenic infections	Exotoxin A
<i>Staphylococcus aureus</i>	Pyogenic infections, enterotoxemia	Alpha, lethal, necrotizing, hemolytic Beta, lethal, hemolytic Gamma, lethal, hemolytic Delta, hemolytic Exfoliating toxin ^a Enterotoxin ^a
<i>Streptococcus pyogenes</i>	Pyogenic infections, scarlet fever, rheumatic fever	Erythrogenic, nonlethal Streptolysin O, lethal, hemolytic, cardiotoxic Streptolysin S, lethal, hemolytic
<i>Vibrio cholerae</i>	Cholera	Cholera toxin, lethal, enterotoxic ^a
<i>Salmonella Typhimurium</i>	Enteritis	Enterotoxin? ^a
<i>Shigella</i> spp.	Dysentery	Enterotoxin ^a
<i>Yersinia pestis</i>	Plague	Murine toxin, cytotoxic pore-forming toxins ^a

^aToxins that produce harmful effects of infectious disease.

Endotoxins

Endotoxins are composed of the LPS portion of the outer membrane on the cell wall of gram-negative bacteria. The cell wall of gram-negative microorganisms is composed of two layers—the inner peptidoglycan layer and an outer membrane. The LPS is contained in the outer membrane along with proteins and phospholipids (see Fig. 2.2). LPS contains three regions: an inner lipid A, a core polysaccharide, and an antigenic oligosaccharide (O region). Lipid A is hydrophobic and anchors LPS in the outer membrane, while the hydrophilic O-region extends a short distance from the cell.

The lipid A portion of LPS is responsible for the toxic activity of endotoxin. Its chemical structure varies among gram-negative bacteria, making some species more virulent than others. LPS stimulates the release of proinflammatory cytokines (e.g., tumor necrosis factor and interleukin 1), chemokines, and other inflammatory mediators that aid in mounting an innate immune response. These are the chemical mediators that produce the effects of endotoxin that consist of dramatic changes in blood pressure, clotting, body temperature, circulating blood cells, metabolism, humoral immunity, and cellular immunity.

Endotoxins stimulate the fever centers in the hypothalamus, increasing body temperature within 1 hour after exposure. Endotoxins can produce severe hypotension within 30 minutes. Septic or endotoxic shock is a serious and potentially life-threatening condition. In contrast with shock caused by fluid loss, such as shock seen in severe bleeding, septic shock is unaffected by fluid administration. Endotoxins also initiate coagulation, which can result in disseminated intravascular coagulation. This process depletes clotting factors and activates fibrinolysis so fibrin-split products accumulate in the blood. These fragments are anticoagulants and can cause serious bleeding. Another feature of patients with endotoxic shock is severe neutropenia, which can occur within minutes after exposure. It results from sequestration of neutrophils in capillaries of the lung and other organs. Leukocytosis follows neutropenia because neutrophils are released from the bone marrow.

Endotoxins also produce a wide variety of effects on the immune system. They stimulate proliferation of B lymphocytes in some animal species, activate macrophages, activate complement, and have an adjuvant effect with protein antigens. They also stimulate interferon production and cause changes in carbohydrate and lipid metabolism as well as sensitivity to epinephrine. A severe infection with gram-negative bacteria can lead to serious and often life-threatening situations. Bacterial exotoxins and endotoxins are compared in Table 2.6.

Case check 2.3

In the Case in Point, diarrhea caused by *C. difficile* was diagnosed in a patient who had been treated with antimicrobial therapy for several days. *C. difficile* produces potent virulence factors, including an enterotoxin called *toxin A* and a cytotoxin called *toxin B*. *C. difficile* is a significant cause of diarrhea in patients who have received prolonged courses of antimicrobial therapy in both outpatient and inpatient settings.

Table 2.6 Differences between bacterial exotoxins and endotoxins

Characteristic	Exotoxins	Endotoxins
Organism type	Gram-positive and gram-negative	Gram-negative
Chemical nature	Simple protein	Protein-lipid-polysaccharide
Stability to heating (100°C)	Labile	Stable
Detoxification by formaldehyde	Detoxified	Not detoxified
Neutralization by homologous antibody	Complete	Partial
Biological activity	Individual to toxin	Same for all toxins

Host resistance factors

Physical barriers

Humans have evolved a complex system of defense mechanisms to prevent infectious agents from gaining access to and replicating in the body. Healthy skin is an effective barrier against infection. The stratified and cornified epithelium presents a physical barrier to penetration by most microorganisms. Only a few microorganisms can enter the body by way of intact skin. Some of these microorganisms and others that normally enter when the skin barrier is compromised are listed in Table 2.7. Most of the organisms listed in Table 2.7 require help in penetrating the skin barrier (e.g., animal or arthropod bite) or microscopic tears. Healthy, intact skin is clearly the primary mechanical barrier to infection. The skin also has substantial numbers of microbial biota that are usually nonpathogenic organisms that contribute to a low pH by their metabolism, compete for nutrients, and produce bactericidal substances (e.g., bacteriocins). In addition, long-chain fatty acids secreted by sebaceous glands are directly toxic to some bacteria and contribute to an acid pH ensuring that relatively few organisms can survive and prosper in the acidic environment of the skin. These conditions prevent colonization by transient, possibly pathogenic organisms.

Because mucous membranes interact with the environment, they are more easily penetrated by pathogenic agents. However, mucous membranes are covered by mucus, a viscous mixture of mucin, glycoproteins, antibodies (primarily IgA), and other antibacterial factors. For a pathogen to colonize mucous membranes and potentially cause an infection, it must overcome these factors. In addition, the epithelium lining mucous membranes is periodically shed, taking away any bacteria attached to the cells. Underlying the mucous membranes are several cells of the immune system including macrophages, dendritic cells, T and B lymphocytes, and innate lymphoid cells.

Cleansing mechanisms

Normally, the term *cleansing* suggests a liquid. However, one of the most effective cleansing mechanisms humans have is

Table 2.7 Microorganisms that infect skin or enter the body via the skin

Microorganisms	Disease	Comments
Arthropod-borne viruses	Various fevers, encephalitides	150 distinct viruses, transmitted by infected arthropod bites
Rabies virus	Rabies	Bites from infected animals
Rickettsiaceae	Typhus, spotted fevers	Bites from infected arthropods
<i>Leptospira</i>	Leptospirosis	Contact with water containing infected animal urine
<i>Staphylococcus aureus</i>	Boils, impetigo	Most common skin invaders
<i>Streptococcus pyogenes</i>	Impetigo, erysipelas	
<i>Bacillus anthracis</i>	Cutaneous anthrax	Systemic disease following local lesion at inoculation site
<i>Treponema pallidum</i> subsp. <i>pallidum</i>	Syphilis	Warm, moist skin is more susceptible
<i>Yersinia pestis</i>	Plague	Bite from infected rat flea
<i>Plasmodium</i> spp.	Malaria	Bite from infected mosquito
Dermatophytes	Ringworm, athlete's foot	Infection restricted to skin, nails, and hair

the desquamation of the skin surface. The keratinized squamous epithelium or outer layer of skin is being shed continuously. Many of the microorganisms colonizing the skin are disposed of with the sloughing of the epithelium.

More obvious is the cleansing action of the fluids of the eye and the respiratory, digestive, urinary, and genital tracts. The eye is continually exposed to microorganisms, which means this organ has some highly developed antimicrobial mechanisms. Tears bathing the cornea and sclera not only lubricate the eye but also wash foreign matter and infectious agents away from the surface. Additionally, tears contain IgA and lysozyme.

The respiratory tract is also continuously exposed to microorganisms and is protected by nasal hairs, ciliary epithelium, and mucous membranes. A continuous flow of mucus emanates from the membranes lining the nasopharynx, which traps particles and microbes and sweeps them to the oropharynx, where they are either expectorated or swallowed. The trachea is lined with ciliary epithelium. These cells have hairlike extensions (cilia) that sweep particles and organisms upward toward the oropharynx. This material is expectorated or swallowed. Heavy smokers have a significant reduction in ciliated epithelial cells and therefore are more susceptible to respiratory infections. The purpose of these mechanisms is to prevent infectious agents and other particles from reaching the bronchioles and lungs. Under normal conditions, they are very effective, and the air moving into and out of the lungs is sterile.

Bacteria are swallowed into the gastrointestinal tract either as part of the mouth biota and upper respiratory tract or in liquids and food. Most bacteria are destroyed by the low pH

found in the stomach. However, some bacteria can survive and pass into the small intestine. The number of bacteria in the intestine increases as the distance from the stomach increases. The distal portion of the colon contains the highest number of organisms. The gastrointestinal tract is protected by mucous secretions and peristalsis that prevent the organisms from attaching to the intestinal epithelium.

The genitourinary tract is cleansed by voiding urine. Consequently, only the distal portion of the urethra typically has a microbial population. The vagina contains a large population of organisms as part of the indigenous biota. The acidity of the vagina, resulting from the breakdown of glycogen by the resident biota, tends to inhibit transient organisms from colonizing. The cervix is normally sterile.

Antimicrobial substances

Various substances produced in the human host have antimicrobial activity. Some are produced as part of the phagocytic defense and are discussed later. Others, such as fatty acids, hydrogen chloride in the stomach, lysozyme, and secretory IgA have already been mentioned.

Lysozyme, a low-molecular-weight (approximately 14 kDa) enzyme found throughout the animal kingdom, hydrolyzes the peptidoglycan layer of bacterial cell walls causing lysis. In some bacteria, the peptidoglycan layer is directly accessible to lysozyme. These bacteria are killed by the enzyme alone. In other bacteria, the peptidoglycan layer is exposed after other agents have damaged the cell wall (e.g., antibody and complement, hydrogen peroxide). In these cases, lysozyme acts with the other agents to cause death of the infecting bacteria. Through evolution, some bacteria exhibit chemical modification of peptidoglycan, increasing resistance to lysozyme. In fact, *S. aureus* is nearly totally resistant to its effects. Lysozyme is found in serum, mucus, tissue fluids, tears, breast milk, saliva, and sweat.

The **complement system** is composed of about 20 proteins, mostly produced by the liver. Many of the proteins are proenzymes, released in an inactive form but ultimately metabolized into an active enzyme. During metabolism, the proenzymes are cleaved into an "a" and "b" component, each with different functions. The outcomes of complement activation are production of opsonins, chemotaxins, and other inflammatory functions. In addition, the proteins form a membrane attack complex that can lyse plasma membranes, such as those of bacteria.

Antibodies, especially secretory IgA, are found in saliva and mucous secretions of the respiratory, genital, and digestive tracts. They may serve as **opsonins**, enhancing phagocytosis, or they may fix complement and neutralize the infecting organism. Serum also contains low-molecular-weight cationic proteins, termed β -*lysins*. These proteins are lethal against gram-positive bacteria and are released from platelets during coagulation. The site of action is the cytoplasmic membrane. These antimicrobial substances and systems work best together. A combination of antibody, complement, and lysozyme is significantly more effective in killing bacteria than each alone or than any combination in which one or more are missing.

Interferons inhibit viral replication and are arguably the most important initial mechanism to control viral infections. Interferons are a group of cellular proteins induced by

eukaryotic cells in response to viral infection or other inducers. Interferons play a significant role in the innate response against foreign invaders. Interferons bind to interferon receptors on cells and produce an antiviral state by activating antiviral genes in both infected and uninfected cells. These gene products can block viral penetration and inhibit viral replication. Uninfected cells that have been exposed to interferon are refractory to virus infection. Interferons also activate macrophages and natural killer cells, enhancing their antiviral activity. Some interferons play a role in the adaptive immune response by stimulating dendritic cells—which are antigen-presenting cells—and T cells. Numerous bacteria, viruses, and their products induce interferon production. Interferon is so named because it can interfere with viral replication.

There are instances in which viruses escape the effects of interferons, either because they are resistant to the antiviral effects or because the induction of interferon in the host does not take place. For example, the vaccinia virus can resist the effects of interferons by inactivating interferon gamma. Other viruses can produce persistent infections because these viruses do not induce interferon production.

Phagocytosis

Phagocytosis is an essential component in the resistance of the host to infectious agents. It is the primary mechanism in the host defense against extracellular bacteria and numerous viruses and fungi. The PMNs, macrophages, and monocytes are the body's second line of defense.

The stem cells for neutrophils arise in the bone marrow, where they differentiate to form mature neutrophils. During this maturation, the cells synthesize myeloperoxidase, proteases, cathepsin, lactoferrin, lysozyme, and elastase. These products are incorporated into membrane-bound vesicles called *lysosomes*. The lysosomes appear as azurophilic granules on Wright's stain and contain enzymes, oxygen-reactive molecules, and other substances necessary for the killing and digestion of engulfed particles. The PMN also has receptors on the cell membrane for some complement components that stimulate cell migration, the metabolic burst, and secretion of the lysosome contents into a phagosome. The PMN, an end-stage cell, has a circulating half-life of 2 to 7 hours and makes up the majority of white blood cells in circulation of healthy individuals. It can migrate to the tissues, where its half-life is less than 1 week.

Macrophages also originate in the bone marrow from stem cells. They circulate as monocytes for 1 to 2 days and then migrate through the blood vessel walls into the tissues and reside in specific tissues as part of the mononuclear phagocyte system. These cells are widely distributed in the body and play a central role in specific immunity and nonspecific phagocytosis (Table 2.8).

Chemotaxis

Four activities must occur for phagocytosis to take place: (1) migration of the phagocyte to the area of infection (chemotaxis), (2) attachment of the particle to the phagocyte, (3) ingestion, and (4) killing. The PMNs circulate through the body followed by movement into the tissues, an action called **diapedesis**, which is the movement of the neutrophils

Table 2.8 Tissue distribution of monocytes/macrophages

Cell name	Tissue distribution
Monocyte	Blood
Kupfer cell	Liver
Alveolar macrophage	Lung
Histiocyte	Connective tissue
Microglial cell	Central nervous system
Mesangial cell	Kidney
Macrophage	Spleen, lymph nodes

Fig. 2.3 Phagocytosis: chemotaxis migration of phagocytes PMNs, Polymorphonuclear neutrophils.

between the endothelial cells of the blood vessels into the tissues. The body is under constant surveillance by these and other phagocytic cells. When an infection occurs, massive numbers of PMNs accumulate at the site. This accumulation is not a random event; rather, it is a directed migration of PMNs into the area needing their services. This migratory process is called **chemotaxis**. Several substances serve as **chemotactic agents** (chemotaxins), which attract phagocytic cells. These include certain complement proteins, several bacterial products, products from damaged tissue cells, and products from responding immune cells. As the organism triggers tissue damage and inflammation, chemotaxis of phagocytes occurs (Fig. 2.3). The speed and magnitude of this response are easily visualized by recalling how quickly a splinter or similar injury causes inflammation and how much pus is produced.

Attachment

The initial contact of the PMN with an invading organism may be random. One of the most effective defenses bacteria have against phagocytosis is the capsule. This structure prevents attachment of the neutrophil's membrane to the organism, which must occur before ingestion can take place. Attachment is facilitated by the binding of specific antibodies or complement proteins to the microorganism. The neutrophil membrane has various receptors, including receptors for the Fc portion of IgG1 and IgG3, and the C3b component of complement. These three factors can bind to the invading

microorganism, resulting in the microorganisms being coated with one or more of these factors. The receptor on the PMN for the specific factor coating the bacterium binds to the factor and forms a bridge that brings the bacterium into close physical contact with the leukocyte membrane. The coating of the bacterium with antibody or complement components results in enhanced phagocytosis by the PMN. This process or phenomenon is called **opsonization**.

Ingestion and killing

The next step of phagocytosis is ingestion. This process occurs rapidly after attachment. The cell membrane of the phagocytic cell invaginates and surrounds the attached particle. The particle is taken into the cytoplasm and enclosed within a vacuole called a *phagosome* (Fig. 2.4). The phagocytosis of a particle triggers a significant increase in the metabolic activity of the neutrophil or macrophage. This increase is termed a *metabolic* or **respiratory burst**. The cell demonstrates increases in glycolysis, the hexose monophosphate shunt pathway, oxygen use, and production of lactic acid and hydrogen peroxide.

The phagosome is acidified by the formation of a proton (H^+) gradient. Highly toxic oxygen-reactive intermediates (e.g., hydrogen peroxide) and reactive nitrogen intermediates (e.g., nitric oxide) are secreted into the phagosome contributing to pathogen killing. Fusion with cytoplasmic granules (lysosomes), producing phagolysosomes, delivers a variety of antimicrobial factors. Lysosomes are vacuoles containing enzymes and other antibacterial components. The list of

Fig. 2.4 Transmission electron micrograph of engulfed bacterial cells inside phagosomes (arrows).

enzymes found within the lysosomes is long—more than 20 enzymes, including proteases, lipases, RNase, DNase, and acid phosphatase. Other antimicrobial agents include lactoferrin, which chelates iron and prevents bacterial growth; lysozyme; and several basic proteins. The usual result is that a phagocytosed organism is quickly killed and digested. Neutrophils naturally contain many lysosomes and are effective at killing phagocytized pathogens. Alternatively, macrophages and monocytes require activation by factors such as interferon gamma and interaction with pattern recognition receptors, discussed later.

Organisms that are intracellular pathogens survive phagocytosis and can multiply within the phagocyte, most notably mononuclear leukocytes. Because PMNs have more lysosomes, intracellular pathogens are much less likely to survive in these cells. Other defense mechanisms must play a major role in immunity to these intracellular organisms. The importance of phagocytosis is seen in patients with defects in the numbers or function of phagocytic cells. Such patients have frequent infections despite possessing high levels of serum antibody. Many of the organisms listed in Table 2.4 are common isolates, which is not surprising because they have developed a means to interfere with phagocytosis, increasing their pathogenicity.

Inflammation

Inflammation is the body's nonspecific response to injury or foreign body. Fig. 2.5 illustrates the components involved in acute and chronic inflammatory responses. A hallmark of inflammation is the accumulation of large numbers of phagocytic cells. These leukocytes release mediators or cause other cell types to release mediators. The mediators cause erythema because of greater blood flow, edema from an increase in vascular permeability, and continued phagocyte accumulation via chemotaxins, resulting in pus. The enzymes released by the phagocytes digest the foreign particles, injured cells, and cell debris. After the removal of the invader, the injured tissue is repaired.

Immune responses

The immune system response to infection is briefly discussed in this chapter to provide the reader with an appreciation of its role and complexity. The balance between health and infectious disease is complex and mediated by humoral and cellular factors. The relative importance of each factor depends on the microbe, route of infection, condition and genetic makeup of the host, and other factors yet to be clearly characterized. For example, a patient with AIDS becomes more susceptible to opportunistic organisms as the immune system deteriorates.

Table 2.9 summarizes the defenses used by the human host against infection. Classically, the term *immunity* has been defined as a complex mechanism whereby the body is able to protect itself from invasion by disease-causing organisms. This mechanism, known as the **immune system**, consists of numerous cells and protein molecules that are responsible for recognizing and removing foreign substances. This general definition has been broadened over the years to mean a reaction to any foreign substance, including proteins and polysaccharides as well as invading microorganisms. Research advances over the years have dramatically increased our

Fig. 2.5 Components involved in acute and chronic inflammatory responses. (From Kumar, V, et al. (2005). *Robbins and Cotran pathologic basis of disease* [7th ed.]. Philadelphia: Saunders.)

understanding of the **immune response** and given us an appreciation of the cellular interrelationships. The immune response can be divided into two broad categories: (1) *innate* or *natural immunity* with little or no specificity and (2) *adaptive* or *specific immunity*, which is highly specialized.

Innate, or natural, immunity

Innate immunity, also referred to as *natural* or *nonspecific immunity*, consists of several components. These include (1) physical and chemical barriers such as the skin and mucous membranes, (2) blood proteins that act as mediators of infection, and (3) a cellular mechanism capable of phagocytosis such as neutrophils and macrophages and other leukocytes such as natural killer cells. Fig. 2.6 shows examples of the innate immune defenses located at different body sites. This first line of defense has a limited capacity to distinguish one organism from another, and previous exposure to a particular foreign substance is not required. Physical barriers, mentioned earlier, may be as simple as the keratinized outer layer of the skin. Also, the secretions along the mucous membranes and the ciliated epithelial cells of the respiratory tract promote trapping and removal of microorganisms. In addition, many secretions provide a chemical barrier, such as the acidic pH of the stomach and vagina. Saliva and tears contain enzymes such as lysozyme, and the sebaceous glands of the skin contain oils and fatty acids capable of inhibiting invasion by pathogenic organisms. The normal biota of these sites adds another dimension to the host's ability to resist invading pathogens.

Once the physical and chemical barriers to infection have been penetrated, nonspecific mechanisms of innate immunity become involved—an animal's second line of defense. Innate

immune system cells have receptors called **pattern recognition receptors** (PRRs) that recognize conserved sequences on the surfaces of microorganisms. The first PRR discovered was the **Toll-like receptor** (TLR). These low-molecular-weight transmembrane proteins contain an extracellular domain that binds the pathogen-associated molecular patterns (PAMPs) that are present on pathogens. Eleven different TLRs (TLR1 to TLR11) have been identified in humans, and each has specificity for components of different microorganisms. For example, TLR4 recognizes LPS from many species of gram-negative bacteria. Recognition of these microbial components by PRRs allows innate immune system cells to initiate the innate immune response. PRRs on phagocytes can recognize PAMPs on pathogens and initiate phagocytosis.

Phagocytic cells ingest and kill microorganisms, while activated complement components contribute to a wide variety of immunologic events, including opsonization and chemotaxis, discussed previously. Collectively, these immunologic defense mechanisms, along with host tissue damage caused by the invading organisms, combine to produce an acute inflammatory response by the host. The importance of natural immune mechanisms rests in their rapid response to invading organisms. However, these mechanisms are effective primarily against extracellular bacterial pathogens, playing only a minor role by themselves in immunity to intracellular bacterial pathogens, viruses, and fungi.

Adaptive, or specific, immunity

Adaptive immunity enhances the protective capability of innate immunity. This arm of the immune response is specific for distinct molecules, responding in particular ways to

Table 2.9 Summary of defenses of the human or animal host to infection and evasion mechanisms attributed to various microorganisms

Host defense	Mechanism of evasion	Microbial example
Hydrodynamic flow	Attachment	Fimbriae, surface proteins, lipoteichoic acid
Mucous barrier	Attachment Penetration	Mannose-sensitive fimbriae, surface proteins Mucinase
Deprivation of essential nutrients (e.g., transferrin)	Systems of high-affinity uptake	Siderophores
Lysozyme in secretions	Resistance to lysis	Modification of peptidoglycan
Surface Igs	Absent or low immunogenicity Antigenic heterogeneity Masking of antigens Destruction of immunoglobulins	Hyaluronic acid, capsules Fimbriae, capsules, LPS, M protein Capsules, IgA-binding proteins IgA protease
Mucous membrane	Penetration	<i>Neisseria gonorrhoeae</i> , <i>Shigella</i> spp.
Serum defenses		
Recognition by antibody	Antigenic heterogeneity Masking of antigen Destruction of antibody Antigenic variation	Fimbriae, capsules, LPS, M protein Capsules, Ig-binding proteins <i>Borrelia</i>
Complement system	Failure to activate alternative pathway Inactivation of complement components Resistance to bacteriolysis Formation of abscess	Sialic acid capsules Cleavage of C3b CoIV plasmid <i>Bacteroides fragilis</i> capsule
Localization		
Fibrin tapping	Fibrinolysis	<i>Streptococcus</i>
Abscess formation	Collagenase, elastase	<i>Pseudomonas</i> , <i>Clostridium</i>
Adaptive immune response	Nonspecific B-cell activation Inhibition of cell-mediated immune response Rapidly fatal (toxin)	LPS, lipoprotein Anergy of miliary tuberculosis and T-cell destruction by HIV Anthrax, plague, <i>Clostridium</i>
Phagocytosis	Inhibition of chemotaxis Inhibition of attachment and ingestion Inhibition of metabolic burst Prevent phagosome-lysosome fusion Resistance to permeability-inducing cationic protein Resistance to oxidative attack Escape from phagosome Destruction of phagocyte	<i>Brucella</i> , <i>Salmonella</i> , <i>Neisseria</i> , <i>Staphylococcus</i> , <i>Pseudomonas</i> Capsules, M protein, Ig-binding proteins, gonococcal pili <i>Salmonella</i> Typhi Mycobacteria Gram-positive cell wall, smooth LPS, polyanionic capsules Catalase, superoxide dismutase, carotenoid pigments <i>Mycobacterium bovis</i> , <i>Legionella pneumophila</i> <i>Streptococcus pneumoniae</i> , <i>Streptococcus pyogenes</i> , <i>Staphylococcus aureus</i> , <i>Pseudomonas aeruginosa</i>

HIV, Human immunodeficiency virus; Ig, immunoglobulin; IgA, Immunoglobulin A; LPS, lipopolysaccharide.

different types of foreign substances and developing memory, which allows for a more vigorous response on repeated exposures to the same invader. Lymphocytes and their products, such as **antibodies**, are the major cellular mediators of the adaptive immune response. Antibodies are produced in response to **immunogens**, substances that can induce an adaptive immune response. An **antigen** is a molecule that can bind specifically to an antibody or T-cell receptor.

An interrelationship exists between the mechanisms of the innate and adaptive responses. For instance, inflammation, a nonspecific response of the innate system, provides a signal that triggers an adaptive immune response. In addition, the activity of **complement** (a component of innate immunity) to invading bacteria is enhanced by the presence of specific antibodies

(components of adaptive immunity). This activation leads to phagocytic clearance and elimination of the bacteria.

The adaptive immune response adds a high degree of specialization to the passive mechanisms of the innate response. The nature of the adaptive immune response varies according to the type of organism and is designed to eliminate it. For example, antibodies are produced by B cells and plasma cells in response to extracellular blood-borne organisms and aid in their elimination. However, the response to intracellular parasites is primarily by T cells that produce chemicals that enhance the activities of the phagocytic cells and a subset of T cells called *cytotoxic T cells*. The nature and origin of these cells are described later. Most importantly, the specific response remembers each time it encounters a particular foreign immunogen.

Fig. 2.6 Innate immune defenses located at different body sites.

This is called *immunologic memory*. Subsequent exposure to that immunogen stimulates an increased and specific defense. The adaptive immune response is the third line of defense and improves significantly the host's defense to infection.

Lymphocytes originate in the bone marrow from stem and progenitor cells. Lymphocytes mature and take up residence in various body tissues and organs, including the thymus, lymph nodes, and spleen. They are a diverse group of cells that can be classified into two major types based on cell surface markers: T (thymus-derived) cells and B (bone marrow-derived) cells. T cells mature in the thymus, while B cells leave the bone marrow as *transitioning B cells* and complete maturation in the spleen. The uniqueness of lymphocytes lies in the presence of specific cell surface receptor molecules that recognize and bind a unique immunogen, activating the cell to divide, differentiate, and secrete numerous effector substances. During embryogenesis, the millions of lymphocytes found in the body have been pre-engineered to recognize a vast array of substances as foreign while learning which substances constitute self. Thus the result of an encounter with the antigen is an expanded clone or clones of activated lymphocytes.

Nature of the immune response to infectious agents

Although both humoral-mediated immunity and cell-mediated immunity are important in protecting humans from a wide variety of infectious agents, each contributes differently according to the type of pathogen and virulence

mechanisms. While B cells play the predominant role in the **humoral immune response**, T cells mediate cellular immunity and play an important role in the humoral immune response. Antigen-presenting cells, like dendritic cells, process antigen and present it to T-helper cells with T-cell receptors specific for each antigen. Some T-helper cells become TH2 cells. Each B cell has surface receptors that recognize only one unique antigen. After antigen binding, the B cell processes the antigen, similar to the dendritic cell, and interacts with a TH2 cell with a T-cell receptor specific for the processed antigen the B cell is carrying. The TH2 cell secretes lymphokines that activate the B cell, triggering multiple cellular divisions and differentiation into *plasma cells* that actively secrete proteins called **immunoglobulins**, or antibodies. All antibody molecules derived from a single clone of B cells are of a single specificity (recognize a unique antigen), identical to the antibody receptor molecule on the original B cell. These antibody molecules circulate in the bloodstream and lymphatics, bathe tissues, and bind to infectious agents or substances to aid the host in eliminating them from the body. The detection and quantification of these antibody molecules, obtained from a patient's serum, constitute the primary goal of diagnosing infectious diseases through serologic methods.

Classification and characteristics of antibodies

Antibody molecules, found in serum and other body fluids and secretions, may be classified into one of five distinct immunoglobulin groups or classes. The classes differ from one another in several ways, including chemical structure, serum concentration, half-life, and activity.

The **immunoglobulin G (IgG)** antibody class constitutes about 70% to 75% of the total serum immunoglobulin pool. Their half-life in serum is 3 to 4 weeks. IgG can cross the placenta to the fetus, conferring some protection in both the pre-natal and the postnatal periods. Structurally, IgG is a protein with a molecular weight of about 150 kDa consisting of four polypeptides (two identical light chains and two identical heavy chains) bridged by several disulfide bonds (Fig. 2.7). Although the amino acid sequence of some regions of the polypeptides is nearly identical among all IgG molecules (conserved regions), one of the ends of each polypeptide is highly variable. These variable regions create two active fragment of antigen binding (Fab) sites on each IgG molecule (see Fig. 2.7). Thus IgG antibodies are said to be *bivalent*—capable of binding two antigen molecules.

Antibodies of the **immunoglobulin M (IgM)** class account for 10% to 15% of serum immunoglobulins. Their half-life in serum is about 5 days, and IgM cannot cross the placenta. A developing fetus in the second or third trimester as well as a newborn may respond to an infectious agent with an IgM antibody response of its own. IgM molecules are large; the molecule has a molecular weight of about 900 kDa and consists of a pentamer or five basic subunits—each composed of two heavy chains and two light chains (similar to an IgG molecule) and linked to another polypeptide chain (J chain) by disulfide bonds (Fig. 2.8). The IgM molecule has up to 10 antigen-binding sites available. IgM is the first antibody class produced in response to an immunogen. Both IgG and IgM antibodies are commonly assayed in a variety of serologic tests. The differences in size and configuration of IgG and

Fig. 2.7 Immunoglobulin G.

Fig. 2.8 Immunoglobulin M (IgM).

IgM molecules result in differences in functional activity of the molecules in serologic tests (Table 2.10).

Immunoglobulin A (IgA) antibodies represent 15% to 20% of the total serum immunoglobulin pool. IgA constitutes the predominant immunoglobulin class in certain body secretions, such as saliva, tears, and intestinal mucosa. Because of this association of IgA with mucosal surfaces, it provides protection against microorganisms invading at those sites. Serum IgA occurs primarily as a dimer composed of two subunits (each similar to an IgG molecule) linked together by a J chain. However, when found in secretions, the molecule also contains a secretory component that stabilizes the molecule. Although significant increases in serum IgA levels may occur in association with certain infections, the function of serum IgA is unclear, and few serologic tests for the diagnosis of infectious disease are designed specifically to detect IgA antibody.

The remaining two immunoglobulin classes, **immunoglobulin D (IgD)** and **immunoglobulin E (IgE)**, are normally found in very low concentrations in serum (<1%). IgE levels increase during infection by numerous parasites and may play a role in eliminating these infectious agents from the host. Total serum IgE levels might increase during parasitic infection, and IgE-specific serologic tests for the diagnosis of

Table 2.10 Immunoglobulin G versus immunoglobulin M

Property	Immunoglobulin class	
	IgG	IgM
Molecular weight	150 KDa	900 KDa
Number of 4-polypeptide subunits	1	5
Number of antigen-binding sites	2	10
Serum concentration (mg/dL)	800–1600	50–200
Percentage of total immunoglobulin in serum	75	10
Ability to cross placenta	+	–
Half-life (days)	23–25	5–8

IgG, Immunoglobulin G; IgM, immunoglobulin M; KDa, kilodalton.

a few parasitic agents have been developed. IgE also plays a role in some allergic (hypersensitivity) reactions, and elevated levels can be detected in these situations. The role of serum IgD during infection is unknown, except that it functions as a receptor on B lymphocytes for antigen.

Primary and secondary antibody responses

After exposure to an infectious agent, the host's acquired humoral immune response may produce various classes of antibody directed to one or more antigens associated with the agent. If the host has not been previously exposed to the antigen, a primary immune response that is characterized by the appearance of IgM antibodies occurs. IgM levels usually peak in 1 to 2 weeks followed by a gradual decline to undetectable levels over the next few months. At the time when IgM levels have nearly peaked, IgG (and in some cases IgA) antibodies become detectable, and their levels continue to increase for about 1 month, surpassing peak IgM levels. IgG levels remain elevated for months and then decline slowly, often persisting at low but detectable levels for years (Fig. 2.9).

A subsequent exposure to the same antigen elicits a secondary or **anamnestic immune response**, which is characterized by a rapid increase in IgG levels, prolonged elevation, and a more gradual decline (see Fig. 2.9). IgM synthesis plays a minor role in a secondary immune response. Serologic tests can distinguish between IgG and IgM antibodies. A positive test result for IgM is considered indicative of a current or very recent infection, whereas the presence of IgG alone suggests a previous infection or exposure. Similarly, the presence of significant levels of IgM (with or without IgG) in a newborn suggests in utero infection. IgM can be synthesized by the fetus but cannot cross the placenta, whereas IgG only in the newborn is indicative of passive maternal transfer of IgG across the placenta, not in utero infection.

Cell-mediated immune response

In contrast with humoral immunity, the primary effector cell in the **cell-mediated immune response** is the T cell. Like with a humoral immune response, antigen-presenting cells process antigen and present it to T-helper cells with T-cell receptors specific for each antigen. After interaction with the processed antigen, some T-helper cells become TH1 cells and undergo activation, differentiation, and cell division. The activated TH1 cell releases several low-molecular-weight

Fig. 2.9 Primary versus secondary response. *IgG*, Immunoglobulin G; *IgM*, immunoglobulin M.

proteins known as **lymphokines** that affect other cells, such as macrophages.

The cell-mediated immune response can also target host cells harboring intracellular pathogens, like viruses, for destruction. Cytotoxic T lymphocytes (CTLs) can recognize foreign antigens on the surface of infected cells. Through direct cell-to-cell contact, CTLs will lyse the target cell. Killing the host cell aborts the replication of the pathogen. Skin tests, such as the purified protein derivative for tuberculosis, can be used as a diagnostic tool to detect previous exposure to a pathogen. The in vitro measurement of cell-mediated immunity is beyond the scope of this book, and in vitro cellular immune function tests are not generally performed in microbiology or serology laboratories. Skin tests are used to detect cell-mediated immune response to some infections (e.g., tuberculosis).

In essence, the wide variety and complexity of infectious agents necessitate flexibility in the immune mechanisms of the host. Immunity to extracellular bacterial pathogens, such as *S. aureus* and *S. pyogenes*, is mediated primarily by antibody functioning either alone (neutralization of toxins and blocking the binding of bacteria to host cells) or with complement and neutrophils (chemotaxis and phagocytosis of bacterial cells). Immunity to intracellular bacterial pathogens, such as *M. tuberculosis*, is primarily cell mediated through the activities of T cells, lymphokines, and macrophages. If antibody is produced, it plays little role in eliminating this pathogen because the pathogen is sequestered (hidden) intracellularly, where antibody cannot reach.

Meanwhile, viral infections often elicit both humoral and cell-mediated immune responses. When viruses are free in the bloodstream or other body fluids, antibody can bind directly to adhesion molecules and neutralize viral particles by blocking attachment to host cells. For example, central nervous system infection by arboviruses (which cause encephalitis) or by certain enteroviruses (which cause meningitis) can be prevented if neutralizing antibody against these organisms is present when the virus reaches the bloodstream and before it enters the central nervous system. However, some viruses cause infections that spread cell-to-cell (e.g., herpes simplex virus); they would not be subject to the neutralizing effect of antibodies. In these cases, cell-mediated immunity plays a predominant role in eliminating the agent.

Immunity to both fungal and parasitic infections is also primarily cell mediated; antibody plays little or no role in

prevention of or recovery from infection resulting from these agents. Although antibodies may not have protective value for certain infectious agents, they nonetheless may have diagnostic and prognostic value in serologic tests. Methods for detecting the presence and significance of antibodies for diagnostic purposes are discussed in [Chapter 10](#).

Mechanisms by which microbes may overcome host adaptive defenses

Despite the host's elaborate defenses, infectious agents are obviously able to establish disease. The strategies that microbes employ to counter the host's defenses consist of inducing tolerance or immunosuppression, antigenic variation, and hiding inside host cells as intracellular parasites. Sometimes the host immune system fails to respond to specific immunogens of the infecting microorganisms. This failure to respond is not necessarily caused by immunosuppression. The inability to induce an immune response to a microbial antigen, referred to as *tolerance*, may be caused by a "weak antigen"—that is, an immunogen or immunogenic component of an organism that is incapable of stimulating an immune response by the host. This lack of response suggests tolerance to this immunogen. Tolerance to an infectious agent may also develop when the infection occurs during fetal life or in a neonate. For example, when infected by the rubella virus, a fetus makes its own antibodies. However, it is believed that the antibodies are often "weak" and unable to contain the infection. Because the T-cell response is also poor, the virus can persist in the fetus and during the neonatal period. Hence, infectious agents can persist if they are able to survive in the host during prenatal infections without producing an overt form of disease.

Certain infectious agents do cause immunosuppression in the infected individual. The decreased immune response is often more far-reaching than simply to the immunogens of the involved pathogen. Viruses, certain bacteria, and protozoans are examples of infectious agents likely to cause immunosuppression in the infected host. These agents multiply in macrophages or in lymphoid tissues. The exact mechanisms of immunosuppression have not been defined for all infecting agents. However, individuals infected with viruses such as Epstein-Barr virus and cytomegalovirus show depressed T-cell or antibody responses to other unassociated immunogens. Reduced immunoreactivity caused by an infectious agent is exemplified by that caused by HIV, which targets CD4⁺ T-helper cells. Because HIV destroys the major cells that defend the host against viral, fungal, and protozoan infections, the infected person becomes susceptible to opportunistic infections caused by these organisms.

Some microorganisms can change their surface antigens systematically during a single infection, while inside the host, evading the host immune defenses. This occurs in relapsing or recurring fever infections with *Borrelia recurrentis*. After an initial incubation period of 2 to 15 days following transmission of the spirochetes from a tick or louse, large numbers of the organism are found in the blood. The infected individual experiences high temperature, rigor, severe headache, muscle pain, and weakness. The febrile period lasts for about 3 to 7 days but ends quickly with the induction of an immune response. However, a similar but less severe course

of symptoms recurs several days to weeks later. The relapses are caused by antigen variation by the borreliae. The original antibody produced has low avidity (weak binding) to the new antigen. Spirochetemia worsens during the febrile period until a new antibody can be produced, and it diminishes between recurrences.

Intracellular parasites such as *Brucella* spp., *Listeria* spp., and mycobacteria avoid the host's immune response by surviving inside infected cells. This evasion strategy used by intracellular pathogens makes them unavailable as targets to the host's immune system. Macrophages that engulfed these microbial species protect them from antibacterial substances (e.g., antibody and complement) and support their growth inside the macrophage. During the exoerythrocytic cycle in liver cells, the malarial parasite *Plasmodium* spp. avoids being a target for the immune response. These parasites also infect red blood cells and cause disease while being protected from the host's defense mechanisms.

Hosts produce antibodies against specific immunogenic stimuli as part of an adaptive immune response. However, if the antibodies produced against an infecting organism are of low avidity or have a weak antimicrobial effect on the infecting organisms, the ability of the infected host to control the infection is decreased. Therefore in certain microbial infections, antibodies, although produced, provide little or no protection to the host.

POINTS TO REMEMBER

- Colonization of the body by microorganisms begins at birth.
- The resident microbial biota present at each site in the body are dictated by nutritional and environmental factors.
- Some species of the microbial biota may be opportunists that are capable of causing disease in an immunocompromised host.
- The microbial biota benefit the normal host by priming the immune system, outcompeting potential pathogens for nutrients, and creating a hostile environment for other microbes.
- True pathogens cause disease in all individuals a high percentage of the time.
- The host defense system against microorganisms includes physical, mechanical, and chemical barriers; components of the innate immune system, such as phagocytes, complement, and the products of inflammation; and components of the adaptive immune response.
- Microbes have mechanisms to evade the host's defenses, including the ability to evade phagocytosis; produce enzymes and exotoxins; induce tolerance in the adaptive immune system or suppress the adaptive immune system; and avoid recognition by the adaptive immune system by varying the antigens present on the surface of the microorganism.

LEARNING ASSESSMENT QUESTIONS

2. Which microorganism would most likely cause an opportunistic infection in the genitourinary tract of a woman of childbearing age?
 - a. *Candida albicans*
 - b. *Chlamydia trachomatis*
 - c. *Neisseria gonorrhoeae*
 - d. *Trichomonas vaginalis*
3. What caused the onset of diarrhea resulting from *Clostridioides difficile* infection in the patient in the Case in Point?
 - a. Stimulation of innate immunity producing intestinal inflammation
 - b. Decrease in the resident normal intestinal microbiota
 - c. Immune suppression from antimicrobial therapy
 - d. Side effect of antimicrobial therapy
4. Which organism(s) would be expected as contaminant(s) of improperly collected blood cultures?
 - a. *Bacillus* spp.
 - b. *Neisseria* spp.
 - c. *Streptococcus* sp. Viridans group
 - d. *Cutibacterium/Propionibacterium* spp.
5. A long-term resident species of bacteria in the gastrointestinal tract produces vitamin K, which is required for blood clotting in mammals. Which type of symbiotic relationship does this represent?
 - a. Commensalism
 - b. Mutualism
 - c. Parasitism
 - d. Sentinelism
6. An infant is born with IgM directed against cytomegalovirus (CMV) in the blood. What does this indicate?
 - a. An in utero CMV infection
 - b. A recent CMV infection in the mother
 - c. A CMV infection in the mother months before delivery
 - d. An outbreak of CMV infection in the delivery department
7. What is the most important benefit a capsule provides to a bacterium?
 - a. Enhances ability to infect host cells
 - b. Acts as a toxin
 - c. Degrades antibodies
 - d. Resists phagocytosis
8. What is the role of inflammation as a host immune defense?
 - a. Antibody production to neutralize invaders
 - b. T-cell activation and lymphokine production
 - c. Accumulation of phagocytic cells at the site of tissue injury
 - d. Cell-to-cell killing by cytotoxic T cells
9. Brucellosis is a disease occurring naturally in livestock like goats and cows. The causative agent can be transmitted to humans by drinking raw milk. Which of the following terms describes this disease?
 - a. Zoonosis
 - b. Vector
 - c. Carrier
 - d. Commensalism
10. Which part of an animal's defense mechanisms is most helpful in eliminating intracellular pathogens?
 - a. Phagocytosis by neutrophils
 - b. Cell-mediated immune response
 - c. Antibody production
 - d. Complement activation

11. What is the difference between resident and transient microbiota?
12. What is the significance of the carrier in the pathogenesis of disease?
13. What determines the composition of the indigenous biota at different body sites?
14. How does the resident microbial biota help protect the host from bacterial infection?
15. In the Case in Point, what virulence factor(s) did the infecting organism use?
16. What is the difference between true pathogens and opportunistic pathogens?
17. What is the difference between exotoxins and endotoxins?
18. What cells and soluble mediators are involved in the innate immune response versus the adaptive immune response? What cells and soluble mediators are involved in the humoral response versus the cellular response?
19. How does an animal's response to extracellular and intracellular parasites differ?
20. What are the steps involved in phagocytosis, and how can microorganisms evade each step?

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Delineate the various roles the laboratory and laboratory scientist play in an infection prevention and control program.
2. Describe the facilities and settings in which an infection prevention and control program is important.
3. Define surveillance and the ways in which surveillance is conducted.
4. Justify an outbreak investigation and the steps followed in an outbreak investigation.
5. Analyze the ways in which a microbiology laboratory can support an outbreak investigation.
6. Define when and how environmental culturing and surveillance cultures may be appropriate in an infection prevention and control program.

7. Identify microorganisms commonly encountered in healthcare-associated infections.
8. Describe agencies and entities to which an infection prevention and control program would provide reports.
9. Discuss educational activities that encompass an infection prevention and control program.
10. Correlate the activities of the laboratory with the safety and prevention activities of an infection prevention and control program.
11. Describe the roles of the microbiology laboratory and the epidemiology program in preparing for disease outbreaks, pandemic events, and potential bioterrorism activities.

Case in point

An 82-year-old man was admitted to an intensive care unit (ICU) from an **extended care facility** (ECF); he was confused and short of breath. His chest radiograph revealed consolidation in the left lower lobe. A bronchoalveolar lavage specimen was sent to the laboratory for culture and antimicrobial susceptibility testing. An endotracheal tube was placed, and the patient was attached to a ventilator for respiratory support. The cultures grew a multidrug-resistant strain of *Acinetobacter baumannii*. Within 3 days, two more patients in the ICU had respiratory cultures positive for *A. baumannii*. Over the next 4 days, three additional ventilated patients had tracheal aspirate cultures that grew the same microbe.

The microbiology laboratory scientist notified the **infection prevention and control (IPC)** team of the unusual occurrence of several isolates of the resistant *Acinetobacter*. The IPC practitioner, microbiology laboratory scientist, ICU nurse manager, and physician in charge of the ICU met to review the situation. Additional patient testing was conducted to identify undetected carriers of the organism. Contact precautions were implemented for the patients. Education was initiated that highlighted hand hygiene practices, and environmental cultures were taken. The occurrence of the multidrug-resistant strain of *Acinetobacter* decreased, and eventually no new cases were observed.

Issues to consider

After reading the patient's case history, consider:

- The role of the microbiology laboratory in an IPC program
- The surveillance of healthcare-associated infections and the required laboratory support
- The information needed in an outbreak investigation
- The role of the laboratory scientist as an educator in IPC
- The need for prompt communication of results of concern to infection preventionists (IPs) in health care settings

Every year, an estimated 722,000 healthcare-associated infections (HAIs) occur that result in 75,000 deaths. Each day, approximately 1 in 31 US patients has at least one HAI. HAIs are infections that originate in health care facilities. These infections cost the health care system countless dollars. An effective infection control program must be established in a health care setting to recognize and prevent HAIs.

With the advent of terrorist activities worldwide, the microbiology laboratory has become an integral part of that area of the infection control program. Whether dealing with emerging diseases, such as the Zika virus in 2016, the SARS-CoV-2 (severe acute respiratory syndrome–coronavirus-2) pandemic in 2019, or reemerging diseases, such as Rocky Mountain spotted fever, the laboratory must stay closely aligned with the infection control activities in the setting that the laboratory serves. **Box 3.1** lists examples of **emerging pathogens** and **reemerging pathogens**.

Infectious agents that have not been previously recognized sometimes appear. Several agents have emerged during the past two decades that include the West Nile virus; the avian influenza virus; the SARS-CoV virus, which is responsible for outbreaks of severe acute respiratory syndrome (SARS); the MERS-CoV virus, which causes Middle East respiratory syndrome (MERS); and most recently, in 2019, the SARS CoV-2

BOX 3.1 Examples of emerging and reemerging pathogens

Emerging pathogens

- Avian influenza virus
- Coronavirus (SARS and SARS-CoV-2)
- Hemorrhagic fever viruses
- West Nile virus
- Zika virus

Reemerging pathogens

- Anthrax (*Bacillus anthracis*)
- Botulism (*Clostridium botulinum*)
- Plague (*Yersinia pestis*)
- Rocky Mountain spotted fever (*Rickettsia rickettsii*)
- Tularemia (*Francisella tularensis*)

virus, the coronavirus that causes COVID-19 (coronavirus disease 2019).

The laboratory, therefore, must quickly learn not only how to rapidly identify these agents in human infections but also how to collaborate with the IP in dealing with these agents in the human population. Questions that the IP must ask include the following:

- How are these infectious agents spread or transmitted?
- What reservoirs can harbor them?
- What is their incubation period?
- What antimicrobial agents can successfully treat them?
- How can the environment be disinfected?

The laboratory scientist, IP, and infectious disease physicians all must combine their knowledge to address these issues. The educational role of the laboratory scientists become evident in teaching specimen collection, specimen transport, disinfection, and safety methods.

The reemergence or potential reemergence of pathogens once thought to be eliminated demands collaboration with the IP. The pathogens that cause Rocky Mountain spotted fever, anthrax, and plague are agents that clinical microbiologists have learned about but, because these diseases are uncommon, are not often identified by microbiology laboratories. The laboratory scientist must relearn information once thought to be of low importance. Media selection, identification techniques, and safety precautions must all be reexamined and implemented. Interaction with the IP strengthens the establishment of prevention and control strategies. This chapter covers the settings, activities, and analytic practices involved in implementing an effective infection control program, specifically from the laboratory scientist's perspective.

General concepts in infection prevention and control practice

The clinical laboratory and laboratory scientists play a vital role in the functioning of an effective infection prevention and control (IPC) program. In some settings, the laboratory scientists provide supportive data; in other settings, they may function as a part-time **infection preventionist** (an **infection control practitioner**) as well as a part-time laboratorian. Not

infrequently, the laboratory scientist may leave the laboratory and become the IP or work as a member of an IPC department. There are multiple pathways to join the discipline of infection prevention, including continuing education, specialized training in infection prevention, and pursuing career opportunities.

As the term implies, *infection prevention and control* involves activities aimed at preventing and reducing the dissemination of infections in persons in broad and varied settings. The field is highly interdisciplinary by definition and incorporates many departments and services in health care facilities. The activities range from surveillance activities to outbreak investigation to data management to education. They require an inquisitive and analytic mind, both of which are characteristics seen in clinical laboratory scientists.

Infection prevention and control in health care settings

IPC practices are important in many health care settings. Table 3.1 lists different health care environments in which infection control practices play a vital role. In all the settings, the goal is to prevent the spread of infectious agents and reduce dissemination of infections by assisting with assessment, planning, implementation, and evaluation of national infection control practices. In **public health** or community settings, the transmission of microorganisms occurs through many events in daily living. Microbes are spread at home, in daycare centers, in schools, in crowds, and by individuals. There are sexually transmitted diseases (STDs), diseases spread by respiratory routes, diseases spread by direct contact, foodborne diseases, and waterborne diseases, all of which occur in the public arena.

Infections occur as community-acquired infections, HAIs, and iatrogenic infections (infections caused by activities of a health care provider such as a physician or therapist). HAIs and iatrogenic infections occur because of instrumentation, increased use of antimicrobial agents, breaks in aseptic techniques, and lack of hand hygiene. In acute care hospitals, HAIs present as surgical site infections (SSIs), central line-associated bloodstream infections (CLABSI), catheter-associated urinary tract infections (CAUTIs), and

ventilator-associated pneumonia (VAP), among others. Over 22,000 SSIs and 62,000 device-associated infections were reported by US hospitals in the 2019 HAI progress report. They are found in adults, teenagers, children, neonates, healthy individuals, and immunocompromised patients.

Ambulatory care settings include outpatient surgery, chronic dialysis, and infusion centers; physician or therapeutic practices; and emergency care facilities (ECFs). Infection control must be practiced in these settings, even though the patients may not be seen again. In ECFs, patients are frequently immunosuppressed by disease, age, or therapy. ECFs include skilled nursing facilities, nursing homes, assisted living centers, rehabilitation centers, and hospice care settings. Because of their suppressed defenses and frequent contact with others, these patients are prime candidates for acquiring infections.

Patients who are at home and receive home care from family or a professional home care provider sometimes acquire infections. Most often, home care involves intravascular-related or device-related care. As in ECFs, the immune defenses of these patients are often suppressed by their disease or therapy.

Communal living programs can also be settings in which infections occur. These community living programs include prisons and behavioral health facilities. In these facilities, infections might be found that are spread by contact (illicit tattooing), by intimate contact with blood and body fluids, or simply by aerosols and droplets from overcrowding.

The microbiology laboratory may receive specimens from any of these settings, all of which represent opportunities for infections to spread and opportunities for infection control to be practiced. Microbiology laboratory scientists must know who their clients are and be poised to insert themselves into infection control activities for the varied customer base.

Infection prevention and control during a pandemic

Because of the high transmissibility of SARS-CoV-2, the Centers for Disease Control and Prevention (CDC) recommends using additional IPC practices during the COVID-19 pandemic, along with standard practices recommended as a part of routine health care delivery to all patients. These practices are intended to apply to all patients, not just those with suspected or confirmed SARS-CoV-2 infection.

In assisted living facilities, nursing homes, and long-term care facilities, given the amass population and close proximity, the risk for spread of SARS-CoV-2 among their residents is high. Residents in these health care settings are often older adults with underlying medical conditions and therefore are at increased risk for severe illness if infected with respiratory and other pathogens. Therefore the CDC recommends source control measures for all persons, including when in a health care setting, and an effective IPC program that is critical in protecting both residents and health care personnel. Recommendations that are specific to these facilities are provided by the CDC that complement but do not replace the general CDC IPC recommendations for SARS-CoV-2 for health care personnel during the COVID-19 pandemic. The complete guidance and recommendations may

Table 3.1 Health care settings involving infection prevention and control

Setting	Description
Public health	Community settings (e.g., daycare centers, schools)
Acute care	Hospitals
Ambulatory care	Outpatient surgery, chronic dialysis and infusion centers, physicians' offices, emergency and urgent care facilities
Extended care	Skilled nursing facilities, nursing homes, assisted living centers
Home care	Skilled nursing provided in the home
Communal living	Prisons and jails, behavioral health facilities, residential schools

be found at <https://www.cdc.gov/coronavirus/2019-ncov/hcp/long-term-care.html>. Key points in the guidance include the following:

- Visitation and physical distancing measures
- ICP guidance for health care professionals on the proper use and handling of personal protective equipment (PPE)
- Guidance about when it may be appropriate for a resident suspected of SARS-CoV-2 infection to “shelter-in-place”
- Quarantine recommendations and management of residents who had close contact with someone with SARS-CoV-2 infection

Infection control surveillance

IPC programs include many activities aimed at preventing the spread of infections. To determine where to most efficiently direct these preventive activities, an effective IPC program must collect data on existing infections. By comparing baseline figures with periodic numbers, the IP can recognize an **outbreak** (sudden increase in the occurrence of a disease), upward trends, and positive effects of interventions. Ongoing, systematic collection of these data and the analysis and interpretation of the details surrounding a disease or event is termed **surveillance**. The laboratory contributes to these records on a daily basis. Prompt and efficient communication with the IP and public health authorities is a critical function of the laboratory’s role in surveillance.

During the COVID-19 pandemic, the World Health Organization (WHO) published surveillance strategies to prevent the spread of the disease. While rigorous public health and social measures were implemented to slow the spread of COVID-19, it is critical that an effectual surveillance is in place to guide ongoing implementation of control measures. The key considerations for and objectives of surveillance include the ability to perform rapid detection, isolation, manage suspected cases, and guide the implementation of control measures. Surveillance programs should also be able to detect and contain outbreaks among vulnerable populations and include mandatory and immediate reporting of notifiable diseases. Lastly, the WHO recommends that surveillance programs assess how the pandemic affects health care systems and society as a whole.

Surveillance definitions

An important part of IPC is surveillance; data can be compared internally, locally, and nationally if standard definitions are used. [Table 3.2](#) lists the common terms used in surveillance and their definitions. The CDC recommends definitions that are generally used in the infection control profession. Most IPs are concerned about infections that are acquired within the health care facility, i.e., HAIs. These infections occur after the patient arrives (generally not within the first 48 hours) and were not incubating in the community before the patient arrived. HAIs can be followed within a setting to determine when infection numbers increase above baseline, thereby requiring investigation and intervention.

Infections are generally defined by site, risk factors, and procedures, as shown in [Table 3.2](#); primary infections are infections that occur at one site (e.g., a primary bacteremia). A primary bacteremia would not have another site as the source

Table 3.2 Surveillance definitions

Term	Definition
Primary infection	Infection related to a single, specific site, not from multiple sites
Bloodstream infection	Infection found in the bloodstream
Central line–associated bloodstream infection (CLABSI)	Bloodstream infection related to the presence of intravascular devices such as a central venous catheter or a peripherally inserted central line (PICC)
Surgical site infection (SSI)	Infection at a site where a surgical procedure was performed; usually risk is stratified by length of surgery, site of infection, degree of anticipated contamination, and some host risk factors
Urinary tract infection	Infection of the urinary tract, frequently associated with a urinary catheter
Ventilator-associated pneumonia (VAP)	Pneumonia in a patient associated with mechanical ventilation

of the infection, as would be seen in urosepsis, in which case the primary site would be the urinary tract. Using primary bacteremia as an example, the laboratorian recognizes a bloodstream infection (BSI) by the recovery of clinically significant organisms from blood cultures, whereas the IP determines whether the infection was healthcare-associated and primary. If the IPC was monitoring CLABSIs, the IP would determine whether the BSI was related to an **intravascular device**. For this reason, the site of the blood culture draw (e.g., peripheral internal jugular catheter, femoral catheter) is important to include with the specimen description on the microbiology laboratory report.

The incidence of SSIs is frequently reviewed by the IP. To the laboratorian, the isolation of pathogens from the surgical site is indicative of postsurgical wound infection; the IP determines whether the infection is superficial or deep or if it was an organ space infection. Therefore the site of the wound culture is an important component of the specimen description on the laboratory report. The IP relates the infection to other risk factors, such as the length of surgery, degree of contamination of the surgical site (gunshot wound to the abdomen vs. hernia repair), and whether any breaks in surgical technique occurred.

Because urinary tract infections (UTIs) are determined by microbial growth from a urine specimen, the method of urine specimen collection should be described and differentiated between a voided clean-catch urine specimen and a specimen collected by catheterization. The definition of a healthcare-associated UTI includes the presence or absence of a urinary catheter. Healthcare-associated pneumonias are difficult to assess from the perspectives of the laboratory and IP. From the IP perspective, the criteria to define a hospital-acquired pneumonia include the presence of an **endotracheal** tube or some other respiratory device and whether the pneumonia was incubating or present when the patient arrived. In the laboratory, the microbiologist should include in the specimen description on the laboratory report the type and source of the respiratory specimens (e.g., bronchoalveolar lavage, tracheal aspirate, expectorated sputum). With sputum specimens, the quality of the specimen, as evaluated by the presence of white

blood cells and single bacterial morphotypes and the absence of squamous epithelial cells in the direct smear, is an important adjunct. The use of these definitions is important for guiding the IP and allowing the comparison of data.

General or targeted surveillance

IPC programs may have all HAIs within the setting under surveillance, or they may be observing for only specific infections because of budget or personnel constraints. In **total surveillance** programs, all infections are recorded and analyzed to determine whether the infections are healthcare-associated. Risk assessments determine whether the situation is high or low risk and whether the infections are occurring in an unanticipated number. The **infection rate**, which is the speed of spread or frequency of an infectious disease within a population, is determined and analyzed to establish whether the number of infections has increased or decreased. These rates can be compared with previous rates in the setting or with rates in similar local or national health care facilities.

There are several ways of calculating infection rates. For example, the SSI rate is defined as the number of infections per number of procedures expressed as a percentage. Infection rates of CLABSI and VAP are calculated as the number of infections per 1000 device days. If an unexpected change in rates is seen, the IP may conduct further investigations to determine, if possible, the cause of the change and to propose a course of action to reverse the situation. Testing of selected patients or environmental sources, called *surveillance cultures*, may be necessary to clarify the source of organisms being transmitted. From the results of the investigation, the IP would recommend appropriate interventions, such as a change in procedure, education, or increased emphasis on hand hygiene. The IP would continue to monitor the infection to determine whether the infection rate decreases.

Unlike in total surveillance, **targeted surveillance** involves a close watch of only specific, high-risk, high-volume procedures. For example, one program may follow only CLABSI in the ICU and SSIs in gynecologic surgical procedures, whereas another program may conduct surveillance on VAP in the neonatal ICU and adult ICU. Which infections to target is largely based on review of previously ascertained data on infection rates (**baseline data**), on recognition of high-volume and high-risk procedures within the setting, and sometimes on requests by others (e.g., insurance companies, physicians). This process is often termed a *risk assessment*. The targeted surveillance may change from year to year, depending on recognized outbreaks or changes in the number of procedures performed. All surveillance data must be carefully collected, use high-quality laboratory data, and be protected from legal discovery, as determined by the risk management team for the setting.

Baseline data

To recognize when infections constitute an outbreak or when an upward trend is occurring, the IPC program must have established baseline data, that is, the historic occurrence of infections over time. Data at the national level derived from the National Healthcare Safety Network (NHSN) can also serve as the baseline data. However, baseline data from within the specific health care setting more accurately reflect events within that setting. The baseline data are collected and analyzed by numbers, by percentages, or by rates per 1000 device days. Baseline data are an important component of the decision making process

regarding which types of infections to target. In 2016, ambitious targets were set for reduction of specific HAI rates between 25% and 50%. These targets were not met by 2020, so much work remains to be done in this area of health care.

Data gathering

Culture review

Many infection control programs rely heavily on a review of culture results, which is initiated informally by the laboratory scientist, who may then inform the IP of what appears to be an increased number of specific isolates. For example, the laboratory scientist may notice the isolation of an increased number of *Serratia marcescens* or *Salmonella* spp. isolates, which may be infrequently seen in this particular health care facility. Or the laboratory scientist might think that there is an unusual number of methicillin-resistant *Staphylococcus aureus* (MRSA) isolates from skin sites in a prison setting. The appearance of an increase in the number of surgical site specimens with various microorganisms may warrant contacting the IP. These are informal data-gathering activities that are significant to the IPC program. To report data, laboratorians use their experience and sense of what is usual regarding types of specimens and microbes encountered.

A more formal data analysis involves the daily review of culture results reported by the laboratory. Such a review requires laboratory-generated results, generally from a laboratory information system (LIS). For example, the IP or microbiologist reviews positive cultures and categorizes them into groups based on sites, units, organisms, or procedures. From this categorization, the IP may recognize a trend, such as an upward trend in the number of *Pseudomonas aeruginosa* isolates from a skilled nursing facility or an increased number of positive cultures in laminectomy patients. Even more important is when the IP determines that there are more *S. aureus* isolates than usual in the home health care setting. In this case, an initiation of detailed investigations may be indicated. These fact-gathering activities are more formal and specific than the informal monitoring done by the laboratory scientist on the basis of experience.

It is critical to establish a relationship between the laboratory and IP, especially when the laboratory is located off-site from the health care setting. This will facilitate communication of concerns identified by the laboratory professional or when changes in laboratory procedures are considered or made. Collaboration is key to effective outbreak control. Diligence is also needed to collaborate on performance improvement projects to reduce infection risks to patients, staff, and visitors.

Case check 3.1

In the Case in Point, a multidrug-resistant strain of *A. baumannii* was recovered from the bronchoalveolar lavage of the index case. Within days, respiratory cultures from a number of patients grew *A. baumannii*. This upward trend was reported to the IP, and intervention measures were administered.

Statistical correlation by interfacing with the LIS offers a more sophisticated data review system for the purpose of **data mining**. In this type of data analysis, a multitude of events

from a database are searched, analyzed, and then reported to the IP. Data mining removes much of the daily details of the culture result review. It also adds other health care parameters to the analysis that are frequently not available to the IP without detailed examination. This type of analysis may require the LIS and other hospital information systems to interface with the data mining system.

No matter how the culture results are screened and analyzed, a timely review is an integral component of an infection control program. Not only are the patients and their health care providers dependent on high-quality microbiology results, but the effectiveness of an infection control program is also dependent on these results.

Cases

The laboratory must be attuned to what is happening in the community and in various community settings in regard to infection control issues. Infection control in the public health arena affects the local microbiology laboratory. For example, there may be an increase in the number of cases of pertussis in surrounding counties. Even though the laboratory in the immediate county may not have seen any *Bordetella pertussis* isolates, it must be aware of these other cases. Similarly, the anticipated appearance of influenza cases is a seasonal occurrence that also influences the activities of a microbiology laboratory. The laboratory can be proactive in educating health care providers on specimen collection and transport if those are unique to a specific public health concern. Awareness of infection control activities within the public health setting allows the laboratory to acquire the necessary media or reagents to meet emerging needs.

Potential infection control issues that might become apparent within a setting can drive activities in the microbiology laboratory. For example, a product used in the health care setting is recalled because of suspected bacterial contamination. Effective communication between the infection control program and microbiology laboratory is needed to establish screening techniques in anticipation of cases involving contaminated products that might arise in the health care setting. Laboratory scientists must increase their knowledge of the specific product, types of specimens to anticipate, and expected isolates, which may be unique or previously unrecognized by the laboratory. Collaboration among the microbiology laboratory, IPC program, and health care customer becomes paramount. Reporting of community-acquired cases to the laboratory and by the laboratory to the IPC team is an important step in surveillance activities.

Laboratory support and data gathering

Besides providing culture results, the microbiology laboratory also provides the IP with other details. These may include specimen contamination rates, numbers of isolates per site, and/or number of isolates per unit within the health care facility. Knowledge of specimen contamination rates helps the IP with the interpretation of culture results and provides guidance in developing educational activities to improve the collection of quality specimens. For example, if respiratory specimens are frequently contaminated with upper respiratory tract microbiota, interpretation of the results for the health care provider and IP becomes more difficult. Contaminated specimens also prove costly for the patient and health insurance payer because they do not provide useful or appropriate information, and cultures might

need to be repeated. Attempts to determine VAP become futile if the specimens are contaminated with upper respiratory tract microbiota. A similar situation is encountered in blood culture contamination, which lessens the likelihood of high-level interpretive abilities. Blood culture contamination rates above 3% are generally considered high and may indicate educational opportunities for the microbiology laboratory and infection control program. However, it is generally difficult to lower the contamination rate below 2%.

The types of pathogens isolated from given specimens represent important information that can be generated by the laboratory to support the IPC program. For example, if *S. aureus* is frequently isolated from skin infections in a jail setting, the health care provider can anticipate the success of antistaphylococcal antimicrobials in routinely treating those infections. If MRSA, however, is more frequently isolated, the health care provider would change the empiric therapy.

The **prevalence** of a particular pathogen is another piece of information that the microbiology laboratory can provide to the IP. Prevalence is the number of cases of a disease that occur in a given moment in time or specific period in a given population. Therefore not only knowing what pathogens are isolated from a given body site but also being familiar with what pathogens are frequently isolated from a given location in a health care facility is important to the IP. For example, a skilled nursing facility may be reassured that the lack of negative air flow rooms is acceptable if *Mycobacterium tuberculosis* has not been isolated from any of its patients in the past 7 years.

Being able to recognize which pathogens are isolated from patients in an ICU may provide the opportunity for the IP to inform health care providers about the effects of **antimicrobial pressure**. For example, if extended-spectrum β -lactamase (ESBL)-producing *Klebsiella pneumoniae* isolates were seen in that ICU, the physicians might be advised to limit the use of antimicrobial agents that tend to induce the formation of ESBLs. The microbiology laboratory then serves as an important adjunct to an infection control program by providing a multiplicity of types of data.

Frequently identified microbes

Although the types of microorganisms seen in HAIs vary among settings, common pathogens are encountered. This discussion of the laboratory's role in IPC addresses some of the common microbes the laboratory scientist will encounter in the health care setting and the typical body sites they infect. [Table 3.3](#) lists some of the most common organisms identified. The most frequent HAIs are pneumonia, SSIs, gastrointestinal illness, UTIs, and primary BSIs.

Public health and community setting

The laboratory serving a public health or community setting is likely to identify infectious diseases of infection control importance that are less frequently seen in other health care situations. Some of the microbes frequently associated in waterborne or foodborne community outbreaks include *Giardia lamblia*, *Cryptosporidium*, *Salmonella*, *Shigella*, and *Campylobacter*. STDs such as chlamydia, gonorrhea, syphilis, and acquired immunodeficiency syndrome are community-acquired infectious diseases identified in public health laboratories and laboratories serving acute care facilities. Some

Table 3.3 Health care settings and common agents of infection control significance

Health care setting	Microorganisms and infectious diseases
Public health	<i>Neisseria meningitidis</i> , <i>Salmonella</i> spp., <i>Shigella</i> spp., <i>Campylobacter</i> spp., <i>Giardia lamblia</i> , <i>Cryptosporidium</i> spp., <i>Chlamydia</i> spp., <i>Treponema pallidum</i> subsp. <i>pallidum</i> , <i>Neisseria gonorrhoeae</i> , HIV, hepatitis B virus, hepatitis C virus
Acute care	<i>Clostridioides difficile</i> , <i>Staphylococcus aureus</i> , MRSA, <i>Enterococcus</i> spp., <i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Pseudomonas aeruginosa</i> , <i>Acinetobacter baumannii-calcoaceticus</i> , coagulase-negative staphylococci, <i>Candida auris</i>
Ambulatory care	Hepatitis B virus, hepatitis C virus, HIV, <i>S. aureus</i> , MRSA, <i>P. aeruginosa</i> , <i>Enterococcus</i> spp.
Extended care facilities, home care	<i>C. difficile</i> , <i>P. aeruginosa</i> , <i>S. aureus</i> , MRSA, <i>Acinetobacter</i> , <i>Enterococcus</i> spp., coagulase-negative staphylococci, <i>C. auris</i> , <i>Candida albicans</i> , scabies
Communal living	<i>S. aureus</i> , MRSA, hepatitis C, <i>Pediculosis</i> spp. (lice), <i>Sarcoptes scabiei</i> (scabies)

HIV, Human immunodeficiency virus; MRSA, methicillin-resistant *Staphylococcus aureus*.

organisms that are important in public health settings may be more likely to be recovered in an acute care hospital but are reported to a public health jurisdiction for the latter to follow up on as a potential outbreak. Examples include agents such as *Neisseria meningitidis*, encephalitis viruses, West Nile virus, and coronaviruses SARS and COVID-19.

Recently, an emphasis has been placed on agents of bioterror. This is the use of infectious agents or microbial and plant toxins to instill terror in a population (see [Chapter 30](#)). Likely agents are those that are uncommonly seen in clinical laboratories, have a significant mortality rate, and can be difficult to diagnose, treat, and control. Examples include *Bacillus anthracis*, *Brucella* spp., *Burkholderia mallei*, *Francisella tularensis*, *Yersinia pestis*, and botulinum toxin, among others.

Acute care setting

Although a great variety of infectious agents can cause concern as HAIs in acute care settings, some are more frequently seen than others. These are listed in [Table 3.3](#). *S. aureus*, especially MRSA, is an important healthcare-associated pathogen that causes BSIs, SSIs, VAP, and other infections. Although community-acquired MRSA has become more prevalent, healthcare-associated MRSA is worrisome because of its resistance to multiple antimicrobial agents and the opportunity to infect a compromised population of patients. Similarly, enterococci are pathogens of concern in HAIs because of their possible resistance to vancomycin and their potential ability to pass this resistance on to other bacteria. Antimicrobial resistance is considered a major threat to human health. Globally, an estimated 1.27 million deaths directly attributable to microbial resistance occurred in 2019. The leading causes of these infections were *Escherichia coli*, *Staphylococcus aureus*, *Klebsiella*

pneumoniae, *Streptococcus pneumoniae*, *Acinetobacter baumannii*, and *Pseudomonas aeruginosa*.

Escherichia coli and other members of the order Enterobacterales, such as *K. pneumoniae*, are common fecal organisms seen in a variety of HAIs in various sites, including BSIs, SSIs, VAP, and UTIs. In patients who are immunosuppressed by disease or therapy, *P. aeruginosa* is seen as a cause of HAIs. *Clostridioides difficile* is an organism whose toxins cause diarrhea in healthcare-associated infections. Recovery of the organism is not the significant finding, but demonstration of the toxin or detection using nucleic acid amplification testing in a symptomatic patient's stool is significant.

Ambulatory care setting

Ambulatory care settings include a variety of different locations. However, the commonly encountered microorganisms of infection control importance do not vary. Many patients have a chronic illness, are immunosuppressed, and have infectious diseases caused by opportunistic pathogens. Other patients are likely to acquire community-acquired infections, such as hepatitis B virus, hepatitis C virus, and human immunodeficiency virus (HIV) infection. Bacterial isolates include pathogens seen in other settings, such as *S. aureus*, MRSA, vancomycin-resistant enterococci (VRE), and *P. aeruginosa*.

Extended care facility and home care settings

Patients in ECFs and home care settings are frequently immunosuppressed by disease or therapy and often need intravascular or other device-related care. The microbes identified in these patients are often opportunistic pathogens. Causative agents of infection control significance identified in these patients include *P. aeruginosa*, *Candida* spp., *S. aureus*, MRSA, VRE, *Acinetobacter* spp., *C. difficile*, and multiple-antifungal-drug-resistant *Candida auris*. The risk for SARS-CoV-2 spreading among these residents is also high.

Communal living

People who are housed together in some form of communal living setting, such as a prison or behavioral health facility, often have common pathogens similar to those in the other settings described earlier. The infectious diseases are more likely related to the activities of the persons in the facility. For example, *S. aureus* and MRSA are recovered from prisoners who practice illicit tattooing with nonsterile shared equipment, whereas lice, scabies, and hepatitis C virus are more frequently seen in behavioral health settings because of the community source of the clients and their intimate contact with skin and belongings, or with blood and body fluids, respectively.

Outbreak investigation

When a sudden increased frequency of a disease above the usual rate or what is expected in a given population or geographic area occurs over a period, an *epidemic* may be suspected. Most cases are presumed to have a common cause or source or to be related to each other in some way. An

outbreak, which may be localized or widespread, similar to an epidemic, may occur when the increase in the incidence of disease is limited in a particular setting. A *cluster* is an aggregate of cases in a given area over a particular period regardless of the number of cases. An epidemic that has spread over several countries or continents and usually affects a large number of people is called a **pandemic**. There are various reasons for initiating and conducting an **outbreak investigation**. One of them is to identify the source so that preventive and control measures that will prevent future episodes of disease are established and instituted. The outbreak investigation also provides the opportunity to learn more about the disease and its severity, the mechanisms for transmission, and the potential for further spread. Although the microbiology laboratory may be first to recognize the event and will likely participate in the outbreak investigation, surveillance data collected by health departments and notifications received by the health department from clinicians who have seen patients with unusual disease presentation may trigger an outbreak investigation.

Local outbreaks

In a given setting, an outbreak may be suspected when an unanticipated increase in infections occurs. Fig. 3.1 shows infection rates that might trigger an outbreak investigation. In this figure, the baseline infection rate is seen for January to August as 3.3 per 1000 catheter days. In addition, the NHSN benchmark of 5.0 per 1000 catheter days is also plotted. In September, the infection rate rose above the baseline and the NHSN benchmark. This might indicate that an outbreak has occurred or that the change in the rate of infections may have other causes. A more detailed investigation would reveal further information.

Case check 3.2

As represented by the Case in Point, an outbreak may also involve the unexpected isolation of a microorganism. During the investigation and introduction of infection control interventions, an epidemiologic curve is created. Fig. 3.2 shows the epidemiologic curve and recovery of the *Acinetobacter* sp. The case first described on the fourth of the month is termed the **index case**, and it was to be determined whether the other infections that followed were related to that case. The investigation used the laboratory results provided by microbiologists.

Widespread outbreaks

Widespread outbreaks occur outside the confines of a given health care setting. These might be found in a statewide or worldwide outbreak (pandemic). An example of a statewide outbreak is the occurrence of diarrheal disease in persons attending a state fair. Fig. 3.3 depicts an **epidemiologic curve** from such an outbreak. This involved reported cases in 565 fair attendees. A total of 47 cultures were obtained, and 26 of those cultures were positive for *Salmonella* spp. Contaminated well water at the fairgrounds was suspected as the source, and increased hand hygiene and use of bottled water were

Fig. 3.1 Plot of the rate of catheter-related bloodstream infections in a medical intensive care unit. Shown are the National Healthcare Safety Network (NHSN) benchmark and calculated monthly infection rate. The increase in the rate above the baseline and above the NHSN benchmark in September would trigger an investigation of a possible outbreak.

Fig. 3.2 Epidemiologic curve of the occurrence of *Acinetobacter* spp. in respiratory specimens in an intensive care unit. Data were gathered as the result of a suspected outbreak. The graph plots the number of patients with *Acinetobacter* spp. infection by the day on which the cases were identified. Both the index case and the point at which infection control interventions were implemented are indicated on the graph.

instituted 5 days after the first case was reported. After the interventions, the numbers of suspected cases decreased. Cases involved individuals from seven states and Canada. Some were food handlers at the fair in addition to fair attendees. Many suspected cases (>500) were reported but not cultured. The *Salmonella* spp. isolates recovered were all the same serotype. Well water, food, and food preparation sites were cultured.

Another example involves the investigation of a potential measles outbreak involving an international flight from Russia to the United States. The patient suspected of being the index case flew from Russia to London, where she changed planes for a flight to New York. She then changed planes in New York for a flight to Chicago, where she lived. The patient was a college student who had visited her parents in Russia

Fig. 3.3 The epidemiologic curve of an outbreak investigation of diarrhea over a 15-day period at a state fair. The number of cases includes suspected cases (black bars) and culture-proven cases (colored bars). Infection control interventions were implemented on day 8 of the outbreak, and the number of cases decreased.

for the summer. While in Russia, she had contact with several young children who had measles. On her return flight to the United States, she complained of a fever but did not develop a rash until she had been home in Chicago for a day.

Imagine the complexity of an investigation of this case. This scenario was recognized as a potential outbreak and not an actual outbreak when the investigation was undertaken. The recognition of measles by the microbiology laboratory set the investigation into motion, not the occurrence of any additional cases. Several issues must be examined.

- Did the student have measles?
- Were passengers on the plane immune?
- Where did the passengers go after their flight landed?
- How does the health department follow up with them?

Because of routine use of a vaccine most, but not all, people in the United States are immune to measles. However, vaccination may not have been successful or given to some individuals. The incubation period for measles is approximately 10 days (8 to 13 days for the fever, 14 days for the rash). People are contagious before the development of the fever and rash. Those who are not immune are susceptible.

All three of these examples (*Acinetobacter* spp., *Salmonella* spp., measles) represent scenarios of potential infectious disease outbreaks. The investigation of these outbreaks depends heavily on the support of the microbiology laboratory to assist in ruling in or ruling out the infection and in identifying cases and sources. Laboratory support is described in detail later.

Pandemic

First identified in December 2019 in Wuhan, China, COVID-19 caused by SARS-CoV-2, a new human pathogen, is a respiratory illness that can be spread from person to person. Cases of COVID-19 spread rapidly around the world. On March 11, 2020, The WHO declared the COVID-19 outbreak a pandemic. To date (19 February 2022), over 422 million cases and nearly 6.55 million deaths have been reported worldwide.

Table 3.4 Steps of an outbreak investigation

Steps	Description
1. Verify diagnosis of suspected cases.	Establish a case definition.
2. Confirm that an outbreak exists.	Be certain that all suspected cases meet the definition.
3. Find additional cases.	Investigate to determine whether additional cases exist.
4. Characterize cases.	Collect as much information as possible about the cases, including people, place, and time elements. Develop an epidemiologic curve.
5. Form a hypothesis.	Establish a "best guess" hypothesis to explain the outbreak.
6. Test the hypothesis.	Evaluate the hypothesis epidemiologically with control groups and data collected.
7. Institute control measures.	Implement intervention activities to prevent and control the outbreak.
8. Evaluate the effectiveness of control measures.	Determine whether the implemented activities have an impact on the outbreak. Does the number of cases diminish or disappear?
9. Communicate the findings.	Document the investigation, and communicate with all involved parties.

In the United States, the first case was identified in a resident of Washington state who had traveled to Wuhan. A remarkable number of cases followed in Seattle and occurred primarily among older adults living in congregant settings such as independent or assisted living communities, long-term care, and skilled nursing facilities. Across the United States, the COVID-19 epidemic has caused several outbreaks that overwhelmed the entire health care system, with the problem growing in scope until mitigation strategies were identified. There have been over 78 million cases and over 900,000 deaths reported in the United States as of February 2022.

Steps of an outbreak investigation

When an outbreak is suspected, steps are taken to investigate the event. The laboratory is integral in several of the steps. [Table 3.4](#) lists the steps that are followed in an outbreak investigation. The first step is to establish a **case definition**. This step ensures that the rest of the investigation is based on a single definition. This may involve the microbiology laboratory in the search for a specific pathogen or the recovery of several pathogens.

The second step is to confirm that an outbreak exists. One needs to be certain that all of the suspected cases match the case definition and that there is more than an expected number of cases. At this point, the investigator seeks as much consultative assistance as possible. The laboratory is frequently asked for additional input.

The third step is to find additional cases that might be added to the initial number of cases. Additional suspected cases may be discovered by more detailed investigation or by the new occurrence of cases. The laboratory might be asked

to review microbiology data from a previous period to determine whether unrecognized cases have occurred.

The fourth step is to gather as much information as possible about the cases with respect to person, place, and time. Persons suspected of being part of the outbreak should be interviewed to find what the victims have in common. An epidemiologic curve may be constructed to assist in the visualization of the outbreak numbers over time.

The fifth and sixth steps are to form a hypothesis about the event and then to test that hypothesis. In the fifth step, a tentative hypothesis is established as a best guess about the likely reservoir, source, and means of transmission. In testing that hypothesis, a control group is established; then the incident and control groups in the event are compared. Again, the microbiology laboratory may provide insight into the hypothesis and its relationship to the control group.

The seventh step in the investigation may actually occur at any point along the investigation timeline. The establishment of interventions to stop the outbreak probably occurs from the initial recognition and heightened awareness of a problem. The formal steps of the intervention process might not be developed until after the hypothesis is developed and tested. Undoubtedly, interventions of some type (e.g., increased hand hygiene) are introduced early in the investigation.

The eighth step, which comes after the development of interventional strategies, is to evaluate the effectiveness of the interventions. Did the outbreak cease or at least decrease in intensity? The ninth step, the final step and one sometimes overlooked, is to communicate the findings of the investigation. This must include a written report that is kept on file and provided to all responsible individuals.

It is not unusual for an outbreak to end before all data have been collected and analyzed. This is probably because of an early intervention. However, an early end to the outbreak does not ameliorate the need for communication and a written report. The information collected can be useful in future outbreaks caused by the same agent.

Investigation support from the laboratory

The microbiology laboratory plays a crucial role in providing investigative support in an outbreak investigation and in the creation of routine surveillance information. The availability of culture reviews, which may result in the initiation of an outbreak investigation, was discussed earlier. Other types of laboratory support are often important as well.

Cultures and serology

In an outbreak investigation and collection of surveillance data, the collection, processing, reporting, and reviewing of pertinent cultures becomes critical. In the *Salmonella* spp. outbreak at the state fair discussed earlier, consider the number of fecal specimens that the health department laboratory processed, although patient cultures are only one component of the investigative activity. Cultures from other sites may provide additional significant information. Well water and food were cultured in addition to specimens from the patients with diarrhea and food handlers. In the outbreak of infections caused by *Acinetobacter* spp., the laboratory may have cultured respiratory therapy equipment and water samples.

One of the major difficulties in a large outbreak (e.g., the state fair outbreak) is the reduced ability to collect and transport specimens from persons from out of state. Individuals may have cultures processed in their home state, but information about these results may be difficult to track and retrieve. In the state fair example, only a few of the affected individuals had cultures processed and the results included in the investigation—565 suspected cases and only 47 cultures. Reasons for this low number of cultures include the following: (1) the diarrhea lasts 24 to 48 hours, and people may not seek medical help; (2) people who live outside the immediate area may not know of the potential outbreak and the need to provide culture material; (3) people do not want to bother with the expense and time spent to collect cultures; and (4) the specimens may be collected too late in the infection or not transported properly, so no organisms are recovered.

In addition to the culture results, the laboratory may be asked to determine the serologic relationship of the isolates.

- Are all the *Salmonella* spp. of the same serotype?
- What is the epidemiologic profile of the serotype?

Both the isolate identification and serologic relatedness may be important determinants in an outbreak investigation.

Antibiograms

Antibiograms, patterns of sensitivity and resistance to antimicrobial agents in bacteria, can often be used in the investigation of an outbreak. As discussed in [Chapter 13](#), there are times when antibiograms must be viewed with suspicion. Although these laboratory data are not always as precise as other results, they may provide guidance about the microbial relatedness of the isolates. [Table 3.5](#) demonstrates comparisons of two antibiograms of isolates with the antibiogram of the index case. If the isolates all had identical antibiograms (e.g., isolate 1) or if some of the isolates were different in their susceptibility patterns (isolate 2), the inclusion or exclusion from the case definitions might be affected. For example, relatively susceptible *S. aureus* can be distinguished from MRSA in an outbreak of skin infections in prisoners.

Table 3.5 Comparison of antibiograms from microbial isolates

Antimicrobial agent	Index case	Isolate	
		1	2
Ampicillin-sulbactam	R	R	S
Piperacillin	R	R	S
Cefepime	R	R	S
Imipenem	S	S	S
Ciprofloxacin	R	R	S
Gentamicin	R	R	S
Tobramycin	R	R	R
Amikacin	R	R	I

I, Intermediate; R, resistant; S, sensitive.

Molecular epidemiology

Molecular epidemiology is the analysis of molecules, such as proteins and nucleic acids, for the detection, identification, and characterization of microorganisms to generate isolate-specific markers to assess epidemiologic relatedness. In identifying SARS-CoV-2 infections, the WHO has endorsed the identification of viral RNA in a patient's biological materials through nucleic acid amplification tests (NAATs) such as reverse-transcription polymerase chain reaction (RT-PCR). A positive result of NAATs targeting at least two different genes, one of which is specific for SARS-CoV-2, provides a final diagnosis of COVID-19. The RT-PCR test remains the "gold standard" for identifying acute SARS-CoV-2 infection. The laboratory has been able to provide a significant and critical contribution to diagnosing an acute SARS-CoV-2 infection through molecular testing. In addition, with serologic testing, the laboratory has been able to detect the presence and extent of an immune response against the virus.

Pulsed-field gel electrophoresis (PFGE) is a strain-typing technique that can be an important adjunct to epidemiologic investigations. In this method, enzyme-digested chromosomal fragments of bacteria are separated electrophoretically. The patterns of the fragments are compared among strains of microbes recovered in a possible outbreak. Strains with dissimilar patterns would be determined to be unrelated. However, if the patterns are similar, the strains can be identified as possibly related. This potential relatedness is an additional epidemiologic tool that can be incorporated into the investigation of an outbreak. PFGE has been used since the 1980s, and it has remained the reference method because of its high discriminatory power, reproducibility, and nearly 100% typeability. A number of other techniques involving primarily amplification of genomic sequences by polymerase chain reaction and gene sequencing are also used to determine relatedness of species in an outbreak.

Environmental culturing

Case check 3.3

As part of an effective IPC program, the microbiology laboratory may be called on to perform cultures of various environmental sites. Recommendations for environmental infection control have been extensively discussed in a CDC document, "Guidelines for Environmental Infection Control in Health-Care Facilities." The environment is rarely implicated in disease transmission, except with immunosuppressed patients. Although environmental cultures are generally to be avoided, as in the Case in Point, there are times when they become an important and often required element of an IPC program.

Air

Usually, infections traced to air quality occur during construction activities in a health care setting. Because microbes in the air can be incriminated in HAIs, cultures of the air can be a component of air quality investigations. Initially, an **infection control risk assessment** should be conducted to determine whether the air is the likely source of infectious particles. Such an assessment is necessary in construction activities and must be done before any decision to culture the air can

be made. The CDC makes no recommendation regarding routine microbiological air sampling before, during, or after construction. If a fungal infection such as aspergillosis occurs during or immediately after construction, an outbreak investigation may be initiated and control measures implemented. Such an investigation may involve collecting environmental samples (e.g., searching for sources of airborne fungi). High-volume air samplers are the preferred method for collection, although settle plates may also be used. The results of these microbiological cultures must be reported to the IPC team and evaluated.

Water

Water is incriminated in outbreaks in many of the settings for which microbiology laboratories provide service. Outbreaks can occur in various environmental situations, such as those associated with contaminated drinking water (e.g., hospitals, ECFs, prisons) or recreational water (e.g., swimming pools, whirlpools, lakes, streams). They may take place in homes, aboard a plane or ship, in a city or state, or in a foreign country. In the United States, an average of 46 waterborne outbreaks were reported each year between 1971 and 2013, resulting in 642,782 outbreak-associated illnesses from 50 states and 6 territories. Waterborne pathogens often cause diarrheal illness. Other waterborne diseases include respiratory illnesses via inhalation of aerosols (e.g., legionellosis), hepatitis (hepatitis A or hepatitis E), skin infections (from *Pseudomonas* spp. or mycobacteria), and central nervous system infections via nasal aspiration (*Naegleria* spp.). Because of these infection control implications, the laboratory must be prepared to offer diagnostic services or recommend laboratories that do offer those services for waterborne pathogens.

Table 3.6 lists examples of waterborne pathogens. Some waterborne agents can be recovered by routine microbiology procedures such as cultures, but others may require specialized techniques. When asked to perform **environmental cultures** of water, the microbiology laboratory must determine which specific pathogens are sought if this information is known. If legionellosis is suspected, for example, the laboratory must have standard operating procedures for recovering this microbe. If the outbreak involves diarrheal diseases of an unknown cause or causes, the recovery techniques must be broader and may require the use of a specialized laboratory. The IPs involved in the outbreak investigation must be consulted before routine culturing of environmental water is undertaken.

Table 3.6 Pathogens related to waterborne infections

Viruses	Bacteria	Parasites
Norovirus	<i>Salmonella</i> spp.	<i>Entamoeba histolytica</i>
Rotavirus	<i>Campylobacter</i> spp.	<i>Giardia lamblia</i>
Hepatitis A	<i>Yersinia enterocolitica</i>	<i>Cryptosporidium</i> spp.
Hepatitis E	<i>Escherichia coli</i> (O157:H7)	<i>Naegleria</i> spp.
	<i>Legionella</i> spp.	<i>Acanthamoeba</i> spp.
	<i>Pseudomonas</i> spp.	
	<i>Mycobacterium</i> spp.	
	<i>Aeromonas</i> spp.	

In some settings, routine water cultures must be performed because of specific guidelines. For example, for chronic dialysis centers, the CDC recommendations include performing bacteriologic assays of water and dialysis fluids at least once a month with standard methods. The IP or managers of the specific area of concern must be familiar with regulations and guidelines addressing water cultures. The laboratory must be aware of the standard methods to ensure that proper procedures and proper media are used. The laboratory scientist, IP, and manager should maintain a close working relationship to ensure compliance with culturing requirements.

Surfaces

The culturing of environmental surfaces should be performed only under the combined direction of the laboratory and IP. In an outbreak investigation, surface culturing may be needed; however, such cultures should not be routinely obtained. The laboratory must be consulted before environmental surface cultures are undertaken to ensure that proper procedures and media are used. The laboratory scientist should be instrumental in the interpretation of the results.

Reporting

The role of the microbiology laboratory does not stop with providing culture results. Depending on statutory requirements, the laboratory might also be responsible for the reporting of certain infectious diseases to public health jurisdictions. Other groups may expect reports as well, such as committees, persons managing specific programs, and the news media.

Reporting to public health

There is a requirement to report the identification or suspicion of certain infectious diseases to local, state, or federal public health entities. As shown in Table 3.7, diseases designated as class A1 are considered public health concerns and must be reported as soon as they are suspected or identified. Some of these requirements are federally mandated, whereas others may be designated by the state. It is imperative that the laboratory scientist knows which infectious diseases are reportable to what agency and in what time frame they are to be reported.

Reporting to committees and programs

Depending on the setting served by the microbiology laboratory, there may be expectations of reports of infectious diseases to committees in that setting. For example, in an acute care hospital, IPC committees may expect reports with various types of microbiological information. Annual antibiograms, lists of reportable diseases, pathogens recovered in certain hospital units, isolates recovered from certain sites, and blood culture contamination rates are examples of reports that might be requested.

In other settings, physicians may expect periodic updates, including antibiograms and pathogen prevalence. They may expect these to be delineated by office practice, physician, site, or patient type. Those making these requests may be

Table 3.7 Examples of reportable diseases^a

Class	Description	Examples
A1	Diseases of major public health concern—reported immediately on recognition of a case, suspected case, or positive laboratory results	Anthrax, botulism (foodborne), cholera, diphtheria, Ebola virus, plague, rabies, smallpox, meningococcal disease, measles, SARS-CoV-2, tularemia, yellow fever
A2	Diseases of public health concern needing timely response—reported by the end of the next business day after recognition of a case, suspected case, or positive laboratory results	Encephalitis (viral), food-borne disease outbreaks, hepatitis A, Legionnaires' disease, pertussis, syphilis, tuberculosis, typhoid fever, vancomycin-resistant <i>Staphylococcus aureus</i> , vancomycin-intermediate <i>S. aureus</i> , tetanus
A3	Diseases of significant public health concern—reported by the end of the work week	Brucellosis, giardiasis, hepatitis B, hepatitis C, Lyme disease, Rocky Mountain spotted fever, trichinosis
B	Diseases reported only by the number of cases—reported by the end of the work week	Chickenpox (varicella), influenza
C	Report of outbreak, unusual incidence, or epidemic—reported by the end of next work day	Blastomycosis, influenza in a health care setting, histoplasmosis, scabies, staphylococcal skin infections, toxoplasmosis

^aThese are reporting regulations from the Ohio Administrative Code and may vary from state to state.

in home health care, extended care, or communal living settings.

Schools and businesses may request updated reports, especially those related to outbreaks that affect their operation. These reports must be tempered by public health needs and individual confidentiality restrictions. Insurance companies and community advocacy groups recently have expressed interest in knowing about infection control rates. Some states require periodic reporting of these rates. The microbiology laboratory may be involved in providing data for these reports.

Reporting to the media

Among the activities of a microbiology laboratory, discussing microbiology and infection control activities with the media (e.g., television, radio, newspapers) may become necessary. Media relations for the laboratory should be discussed with the risk management area associated with the laboratory. Media relations represent an educational opportunity that might be investigated before the laboratory scientist speaks to media personnel. One must balance the public's need for knowledge as perceived by the news media with privacy restraints for the patient, laboratory, and setting.

Education

Laboratory scientists and infection prevention and control practitioners

The role of the microbiology laboratory in education is a further extension of its activities related to infection control. Laboratory scientists must not only keep themselves educated in their contribution to the IPC team, but also keep the infection control personnel educated regarding the laboratory's contribution to the team. Seminars, scientific articles and books, computer-based learning, and discussion with infection control personnel are ways in which laboratory scientists can maintain their knowledge of infection control and laboratory techniques that can aid the infection control program. The laboratorian should continuously educate the IP regarding the abilities of the laboratory in contributing meaningful information to the IPC committee. As new techniques become available or old techniques are replaced, the laboratory scientist must relay this information to the IP.

Similar information must be provided for others associated with the health care setting and IPC program. Ancillary personnel, such as housekeeping and maintenance personnel, benefit from knowing the laboratory perspective of an IPC program:

- What cleaning and disinfecting agents work against viruses?
- How long does the agent need to be in contact with the environment to inactivate the virus?
- When do the maintenance personnel need to worry about fungi?
- What does mold growing on wet drywall look like?

These and other questions arise among ancillary health care personnel, and the laboratory scientist must be prepared to respond.

Consultation with the microbiology laboratory often is sought when construction is anticipated. Sometimes this education must be provided, even when it is not sought.

- Which microbes may be harbored in standing water?
- When should high-efficiency particulate air (HEPA) filters be used?
- What infectious agents might spread through a facility if proper barriers are not used to control demolition dust and debris?

These are some questions that might be addressed by the microbiology laboratory scientist while acting as a consultant to the infection control program.

Safety

The infection control program affects the microbiology laboratory by emphasizing the need for laboratory safety. As discussed in [Chapter 4](#), safety in the microbiology laboratory encompasses the IPC program. Hand hygiene is a critical part of laboratory safety. Hand hygiene involves handwashing when hands are soiled or the use of alcohol hand rubs

Case check 3.4

Whereas the investigation could not conclusively determine why the outbreak in the Case in Point occurred, the use of contact precautions and improved hand hygiene stopped new cases. It is likely that the causative agent, *A. baumannii*, was in the hospital environment and was spread among the patients by improper hygiene. The presence of a ventilator in the affected patients bypassed host defenses in the compromised patients.

when hands are not soiled. The practice of **standard precautions** further extends infection control to the microbiology laboratory. Gloves must always be worn when blood or body fluids are handled. Proper disposal of microbiological waste, according to state or local regulations and national guidelines, is another critical component of the infection control program in the microbiology laboratory. Receiving available vaccines and testing for diseases such as hepatitis B, influenza, meningococcus, and tuberculosis are steps to protect laboratory personnel. All of these functions connect the microbiology laboratory safety program and the infection control program.

Response plans

With the potential use of biological agents in terrorism and emerging pathogens associated with pandemics, the development of **emergency response plans** is paramount. The microbiology laboratory is an integral part of this infection control activity. Safety, specimen collection, agent identification, and agent control are components of the response plan to which the laboratory can contribute its input. Whether in everyday activities or activities in response to an outbreak or emerging diseases, the microbiology laboratory and laboratory scientists constitute a critical component of an efficient and successful infection control program.

POINTS TO REMEMBER

- The microbiology laboratory interacts with the infection preventionist and infection prevention and control committee in many different health care settings.
- Surveillance is important to establish baseline data and recognize the need to investigate potential outbreaks.
- The microbiology laboratory supports outbreak investigations by providing consultative services including epidemiologic correlation of isolates.
- Although infrequently performed, environmental cultures may play a role in outbreak investigation.
- Microbiology laboratory scientists must recognize their role in providing reports to health departments, committees, the infection prevention and control program, and on occasion, the public.
- The microbiology laboratory must maintain competencies in new techniques and the identification of reemerging and emerging infectious diseases.

- In anticipation of potential bioterrorism events and pandemics, the microbiology laboratory must be equipped to participate in emergency preparedness programs.

LEARNING ASSESSMENT QUESTIONS

- Surveillance is defined as:
 - The systematic collection and analysis of data
 - The review of healthcare-associated infections in laboratory personnel
 - The recognition of emerging pathogens
 - The development of an infection control risk assessment
- Microbes commonly encountered in healthcare-associated infections in hospitals include:
 - Salmonella* spp., *Shigella* spp., hepatitis C virus, *Neisseria meningitidis*
 - Staphylococcus aureus*, *Pseudomonas aeruginosa*, MRSA, *Escherichia coli*
 - Pseudomonas aeruginosa*, *Salmonella* spp., hepatitis C virus, *Giardia* spp.
 - All of the above
- Pulsed-field gel electrophoresis (PFGE) might be performed to:
 - Identify staphylococcal species
 - Assist in an outbreak investigation
 - Develop a new isolation precaution
 - All of the above
- The occurrence of surgical site infections is generally calculated as:
 - The rate of infections in 1000 device-related events
 - The percentage of infections in 100 device-related events
 - The percentage of infections in surgical sites or procedures
 - The rate of infections per 100 hospital days
- Health departments frequently require the reporting by the laboratory of:
 - Diseases of major health concerns (e.g., smallpox)
 - Diseases needing timely response (e.g., foodborne outbreaks)
 - Outbreaks of public health concern (e.g., scabies)
 - All of the above
- Microbial pathogens of potential bioterrorism activity include:
 - Bacillus anthracis*, *Staphylococcus aureus*, West Nile virus
 - Yersinia pestis*, *Staphylococcus aureus*, hepatitis C virus
 - Bacillus anthracis*, *Yersinia pestis*, *Francisella tularensis*
 - Bacillus anthracis*, *Escherichia coli*, coronaviruses
- Environmental cultures are usually to be avoided, except in:
 - An outbreak investigation
 - The occurrence of infections following construction
 - Compliance with specific regulatory requirements
 - All of the above
- The formal steps in an outbreak investigation include:
 - Establishing a case definition and culturing air and water
 - Establishing a case definition, forming and testing a hypothesis, and communicating findings
 - Forming and testing a hypothesis, performing PFGE, and calculating an infection rate
 - Confirming an outbreak exists, calculating an infection rate, and performing serology and culture tests
- Infection prevention and control programs rely on microbiology laboratory support in:
 - Public health settings
 - Acute care facilities
 - Home care settings
 - All of the above
- The microbiology laboratory interacts with the infection prevention and control program by providing:
 - Culture results
 - Antibiograms and pathogen prevalence reports
 - Environmental cultures when appropriate
 - All of the above

Control of microorganisms: disinfection, sterilization, and microbiology safety

Michelle M. Jackson*

CHAPTER OUTLINE

Disinfection and sterilization, 66

Sterilization versus disinfection, 66

Factors that influence the degree of killing, 67

- Types of organisms, 67
- Number of organisms 67
- Concentration of disinfecting agent, 68
- Presence of organic material, 68
- Nature of the surface to be disinfected, 68
- Contact time, 68
- Temperature, 68
- pH, 68
- Biofilms, 68
- Compatibility of disinfectants, 68

Methods of disinfection and sterilization, 69

- Physical methods, 69
- Chemical methods, 70

Disinfectants versus antiseptics, 71

- Alcohols, 71
- Aldehydes, 72
- Halogens, 72
- Chlorine and chlorine compounds, 72
- Detergents: quaternary ammonium compounds, 73
- Phenolics, 73
- Heavy metals, 74
- Gases, 74

EPA regulations on chemical surface disinfectants, 75

FDA regulations on chemical skin antiseptics, 75

- Hygienic handwashing and waterless handrubs, 76
- Surgical hand scrub and waterless surgical handrubs, 77
- Presurgical skin disinfection, 77

Microbiology laboratory safety, 77

General laboratory safety, 78

- Safety program for the clinical laboratory, 78
- Hazardous waste, 85
- Chemical safety, 85
- Fire safety, 96
- Storage of compressed gases, 97
- Electrical safety, 97
- Miscellaneous safety considerations, 97

Bioterrorism and the clinical microbiology laboratory, 98

- Laboratory response network, 98
- Safety during a possible bioterrorism event, 98
- Packaging and shipping of infectious substances, 98

Bibliography, 100

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Define the following terms: *sterilization*, *disinfection*, and *antiseptic*.
2. Differentiate the functions and purposes of a disinfectant and an antiseptic.
3. Describe the general modes of antimicrobial action.
4. Describe the way each physical agent controls the growth of microorganisms.
5. Give the mechanism of action for each type of chemical agent commonly used in antiseptics and disinfectants.
6. Describe the different heat methods and their respective applications.
7. Describe Environmental Protection Agency regulations on chemical surface disinfectants and Food and Drug Administration regulations on chemical skin antiseptics.
8. Discuss the appropriate use of the following skin antiseptics in health care settings by health care personnel: handwash or handrub, surgical hand scrub or surgical handrub, and patient preoperative skin preparation.
9. Describe the hazards that can be encountered in a microbiology laboratory.
10. List the elements included in an exposure control plan.

*This chapter was prepared by the author in her private capacity. No official support or endorsement by the Food and Drug Administration is intended or implied.

11. Discuss the practice of standard precautions.
12. Differentiate standard precautions and transmission-based precautions.
13. Define and give examples of engineering controls, work practice controls, and personal protective equipment.
14. Discuss the World Health Organization classification of infectious microorganisms by risk group.
15. Compare the three types of biological safety cabinets.
16. Differentiate the four categories of biosafety levels.
17. Given an infectious agent and test procedure, justify the appropriate safety precautions to use to ensure that an exposure event does not occur.
18. Explain the information that must be included in safety data sheets.
19. Describe the components of basic fire safety and electrical safety within the microbiology laboratory.
20. Discuss the special safety considerations that must be addressed in the clinical microbiology laboratory during a possible bioterrorism event.

KEY TERMS

Antisepsis	Laboratory response network
Antiseptic	Microbial load
Biofilms	Moist heat
Biological safety cabinet (BSC)	National fire protection association (NFPA)
Biosafety level (BSL)	New drug application (NDA)
Bloodborne pathogens	Over-the-counter (OTC)
Disinfectants	Pasteurization
Disinfection	Patient preoperative skin preparation
Employee right-to-know	Personnel protective equipment (PPE)
Engineering controls	Persistent
Environmental Protection Agency (EPA)	Prions
Exposure control plan	Resident biota (flora)
Fast-acting antiseptic	Risk groups
Filtration	Safety data sheets (SDSs)
Food and Drug Administration (FDA)	Sentinel laboratories
Generally recognized as safe and effective (GRASE)	Sporicidal
Germ theory of disease	Standard precautions
Hazard-rating diamond	Sterilization
Health care antiseptic drug products	Surgical hand scrub
Health care personnel handwash	Transmission-based precautions
Laboratory-acquired infection (LAI)	Transient biota
	Work practice controls

Case in point

Dr. Adams is a geriatrician at a busy metropolitan medical clinic. When she arrives at the clinic, the patients waiting for her in the waiting room are practicing social distancing and wearing masks because of the COVID-19 pandemic. She washes her hands immediately and then uses an alcohol-based hand sanitizer. As she opens the examining room door to see her first patient, Mrs. Jones, the patient notices that Dr. Adams opened the door with her bare hands and is about to examine her. Mrs. Jones tells the doctor to wash her hands first or use the

hand sanitizer before she proceeds with examining her. How should Dr. Adams respond?

Issues to consider**After reading the patient's case history, consider:**

- Potential risks that the physician is taking in spreading infectious agents to her patients
- Importance of handwashing and use of an appropriate antiseptic
- Quality control plan to minimize the risks to patients

Disinfection and sterilization

Safety in the laboratory cannot be overemphasized. Quantification of the risk of working with an infectious agent is difficult. Risk to an individual increases with the frequency and type of organism and level of contact with the agent, as demonstrated by the Case in Point. Each laboratory must develop and institute a plan that effectively minimizes exposure to infectious agents. This chapter provides information on standard disinfection and sterilization techniques for the clinical laboratory. It presents an overview of the following topics:

- Sterilization and disinfection
- Chemical and physical methods of disinfection and sterilization
- Principles and application of each method
- Common disinfectants and antiseptics used in health care settings
- Principles and applications of disinfectants and antiseptics
- Regulatory process of disinfectants and antiseptics

This chapter also covers laboratory safety guidelines for the clinical laboratory practitioner to ensure proper protection and reduce risks of exposure to potentially hazardous biological agents.

Sterilization versus disinfection

The scientific use of **disinfection** and **sterilization** methods originated more than 100 years ago when Joseph Lister introduced the concept of aseptic surgery using carbolic acid, now called *phenol*. Since then, the implementation of effective sterilization and disinfection methods has remained crucial in the control of infections in the laboratory and health care facilities (healthcare-associated infections).

To understand fully the principles of disinfection and sterilization, we must have accurate definitions of certain terms. *Sterilization* refers to the destruction of all forms of life, including bacterial spores. By definition, there are no degrees of sterilization—it is an all-or-nothing process. Chemical or physical methods may be used to accomplish sterilization. The term *sterile* is relevant to the method used. For example, a solution that has been filtered through a certain pore-size filter (<0.22 μm) is often referred to as *sterile*. Even though the filtered solution may be free from large microorganisms

such as bacteria and fungi and their spores, in actuality, any infectious agents (e.g., viruses) that are smaller than the pore size of the filter were not removed; therefore the filtered solution can still contain infectious particles. *Disinfection* refers to a process that eliminates a defined scope of microorganisms, including some spores. Physical or chemical methods may be used, but most **disinfectants** are chemical agents applied to inanimate objects. A substance applied to living tissue (e.g., skin) for the purpose of eliminating or reducing the number of bacteria present is referred to as an **antiseptic**. Antiseptics do not kill spores.

Factors that influence the degree of killing

Before discussing methods used to kill microorganisms, a review of the factors that influence the degree of killing of organisms is important. The following factors play a significant role in the selection and implementation of the appropriate method of disinfection:

- Types of organisms
- Number of organisms
- Concentration of disinfecting agent
- Presence of organic material (e.g., serum, blood)
- Nature of surface to be disinfected
- Contact time
- Temperature
- pH
- Biofilms
- Compatibility of disinfectants and sterilants

Types of organisms

Organisms differ greatly in their ability to withstand chemical and physical treatment (Fig. 4.1). This variability is caused by the biochemical composition of microorganisms and various mechanisms that they can use to protect themselves. For example, bacterial endospores have coats rich in proteins, lipids, and carbohydrates as well

as cores rich in dipicolinic acid and calcium, all of which protect the spores. Cell walls of mycobacteria are rich in lipids, which may account for their resistance to chemical and environmental stresses, particularly desiccation. In contrast, viruses containing lipid-rich envelopes are more susceptible to the effects of detergents and wetting agents. Microorganisms living together in communities, referred to as **biofilms** (see Chapter 31), also provide protection to the microorganisms against chemical and physical means of destruction.

The organisms known today to be the most resistant to the actions of heat, chemicals, and radiation are **prions**. Prions are small, naked infectious proteins. Prions are thought to be the cause of a number of degenerative diseases of the nervous system, e.g., transmissible spongiform encephalopathies ("mad cow disease," Creutzfeldt-Jakob disease). These agents are transmitted to humans through contaminated medicinal products, therapeutic devices, body fluids, and food products. These infectious agents are extremely resistant to chemical and physical methods of destruction. Prions can withstand temperatures exceeding 121°C for several hours while immersed in acid or basic solutions. It is best to handle all body secretions as potentially being contaminated with this agent. When an object or material is thought to be contaminated with a prion, special methods must be taken to destroy the agent. Simple disinfection or sterilization may not be sufficient.

Number of organisms

Another factor to consider is the total number of organisms present, referred to as the **microbial load** (bioburden). If the number of organisms is plotted against the time they are exposed to the killing agent (exposure time) logarithmically, the result is a straight line (Fig. 4.2). The death curve is logarithmic. Because the microbial load is most likely composed of organisms with differing degrees of susceptibility to killing agents, not all of the organisms die at the same time. The microbial load determines the exposure time that is necessary for 99.9% elimination of the microorganisms. In general, higher numbers of organisms require longer exposure times.

Fig. 4.1 Different types of organisms and their resistance to killing agents.

Fig. 4.2 Effect of exposure time versus number of organisms.

Concentration of disinfecting agent

The concentration of a disinfecting agent is also important. The amount of disinfectant needed to destroy microorganisms varies with the different agents. Manufacturers' instructions on preparation, dilution, and use must be followed very carefully. Concentrated disinfectants, such as povidone-iodine, may actually allow microorganisms to survive because there is not enough free iodine to kill microorganisms. Proper concentrations of disinfecting agents ensure the inactivation of target organisms and promote safe and cost-effective practices.

Presence of organic material

Organic material, such as blood, mucus, and pus, affects killing activity by inactivating the disinfecting agent. In addition, by coating the surface to be treated, organic material prevents full contact between the object and agent (see the "Glutaraldehyde" section later in this chapter). Bleach (sodium hypochlorite) is easily inactivated by organic material. For optimal killing activity, instruments and surfaces should be cleaned of excess organic material before disinfection.

Nature of the surface to be disinfected

Certain medical instruments are manufactured of biomaterials that exclude the use of certain disinfection or sterilization methods because of possible damage to the instruments. For example, endoscopic instruments are readily damaged by the heat generated in an autoclave. Alternative methods must be used for this class of instruments.

Contact time

The amount of time a disinfectant or sterilant is in contact with the object is critical. Too little contact time does not allow the agent to work properly. The contact time is a function not only of the agent itself but also of the bioburden on the object, the type of microorganism that is to be killed, and the presence of organic material and the temperature at which the agent is being used. When disinfecting or sterilizing a contaminated object, it is critical to know what organisms may be present and the contact time to use, which is based on the microorganism that is most resistant. The amount of time that an

agent is in contact with an object can also determine whether it is disinfecting or sterilizing the object. For example, glutaraldehyde can be used as a disinfectant or a sterilant, with the difference being the amount of time glutaraldehyde is in contact with the contaminated object. When glutaraldehyde is used as a sterilant, the contact time is much longer than when it is used as a disinfectant. Alcohol and iodine preparations (e.g., Betadine) must be in contact with an object for at least 1 to 2 minutes for them to kill microorganisms. The spores of both bacteria and fungi must be in the presence of disinfectants or sterilants for a much longer time than their vegetative counterpart before they are killed.

Temperature

Disinfectants are generally used at room temperature (20° to 22°C). Their activity is generally increased to some degree by an increase in temperature and decreased by a decrease in temperature. A disinfectant that is used on the workbench generally works faster than if the disinfectant is used on a cold surface such as the walls of a refrigerator. Disinfection of blood spills in a refrigerator can take longer than disinfection of blood spills on a room temperature countertop. Disinfectants and sterilants can be rendered inactive by too high or too low a temperature.

pH

The pH of the material to be disinfected or sterilized can affect the activity of the disinfecting or sterilizing agent. It is critical to make sure at what pH the agent is active and what the pH of the material to be exposed to the agent is at the time the process will be done.

Biofilms

Biofilms are a community of bacteria or other microorganisms. These communities are generally layers of microorganisms that often have a protective material over them that shields them from outside environmental factors. These microbial communities can be on the surface of either inanimate or animate objects. A critical place where biofilms are seen in the hospital is on catheters. Other places may be inside pipes that carry water and on deionizing columns used to make processed water. When dealing with the disinfection of objects that may have a biofilm, it is critical to realize that the presence of the biofilm makes disinfection more difficult. Microorganisms in a biofilm can be characteristically different than when they are planktonic, or singular and free floating. This means disinfectants that the microbes are susceptible to singularly can be resistant within a biofilm (sessile). To disinfect materials that may have a biofilm present, the concentration of the disinfectant may need to be increased, the contact time may need to be increased, or both.

Compatibility of disinfectants

A common mistake is to believe that two disinfectants are better than one. This is not necessarily incorrect, but when more than one disinfectant is used, the compatibility of the disinfectants must be taken into consideration. Some disinfectants may inactivate other disinfectants. For example, the use of

bleach and a quaternary ammonium compound together may negate the activity of both disinfectants.

Whether a chemical agent or physical method is to be used on living tissue or an inanimate object affects the method choice. Clearly, strong, harsh treatments are more effective at inactivating viruses and killing bacteria. However, these treatments would be inappropriate for use as an antiseptic. Bleach is used commonly as a disinfectant to cleanse a laboratory bench, but it is too toxic to be used on the skin as an antiseptic before a venipuncture.

Methods of disinfection and sterilization

Having discussed the way factors that affect the survival of microorganisms influence disinfection and sterilization, we now look at the ways in which methods are selected. E. H. Spaulding categorized medical materials into three device classifications:

1. Critical materials
2. Semicritical materials
3. Noncritical materials

Critical materials are those that penetrate sterile tissues or enter the vascular system. These materials are most likely to produce infection if contaminated, and they require sterilization. Semicritical materials contact mucous membranes, which often contain a normal microbiota. Before these materials are used, they require high-level disinfection agents.

Noncritical materials require intermediate-level to low-level disinfection before contact with intact skin. High-level disinfectants have activity against bacterial endospores, whereas intermediate-level disinfectants have tuberculocidal activity but not **sporicidal** activity. Low-level disinfectants have a wide range of activity against microorganisms but do not demonstrate sporicidal or tuberculocidal activity. [Table 4.1](#) presents a summary of these principles.

Physical methods

As mentioned earlier, sterilization and disinfection can be performed by both physical and chemical methods. Although several physical methods are available, this discussion is restricted to the methods most commonly used in a laboratory or hospital setting.

Heat

Because of its reliable effects, ease of use, and economy, heat is the most common method used for the elimination of microorganisms. Heat can be used in several ways. **Moist heat**, or *heat under steam pressure*, is the principle of autoclaves. Steam under 1 atm of pressure, or 15 psi, achieves a temperature of 121°C. At this temperature, all microorganisms (except for prions) and their endospores are destroyed within approximately 15 minutes of exposure. The time varies according to the density of the material; important factors are that the moisturized heat comes in contact with the material and the contact time is sufficient. An added advantage of moist heat is the shorter time required for sterilization than for dry heat sterilization. Heat in water is transferred more readily

Table 4.1 Device classification and methods of effective disinfection

Device classification	Disinfection method	Killing action against				
		Spores	Mycobacteria	Nonlipid viruses	Fungi	Bacteria
Critical	Sterilization					
	Steam	+	+	+	+	+
	Dry heat	+	+	+	+	+
	Gas	+	+	+	+	+
	Chemical	+	+	+	+	+
	Ionizing radiation	+	+	+	+	+
Semicritical	High-level disinfection					
	2% glutaraldehyde	±	+	+	+	+
	Chlorine dioxide	±	+	+	+	+
	Pasteurization	–	+	+	+	+
	Low-level disinfection					
	Sodium hypochlorite	–	+	±	+	+
	Quaternary ammonium compounds	–	–	±	+	+
	Ethyl alcohol, isopropyl alcohol (60%–90%)	–	–	+	+	+
	Phenolics	–	±	+	+	+
	Iodophors	–	–	+	+	+

+, Positive kill; –, no kill; ±, variable.

to a cool body than heat in air. Moist heat is the sterilization method of choice for heat-stable objects.

Dry heat may also be used as a sterilizing agent, although it requires much longer exposure times and higher temperatures than moist heat. This method can be used for heat-stable substances that are not penetrated by moist heat, such as oils. Dry heat is commonly used to sterilize glassware. Incineration in a flame (e.g., Bunsen burner) or an electric incinerator rapidly destroys infectious agents. However, its use is limited to flame-resistant objects such as metal microbial inoculating loops and needles.

Boiling and **pasteurization** are methods that achieve disinfection but not sterilization; these methods do not eliminate spores. Boiling (100°C) kills most microorganisms in approximately 10 minutes. Pasteurization, used mostly in the food industry, reduces food borne pathogens and organisms responsible for food spoilage. It is generally performed at 72°C (161°F) for 15 seconds. The main advantage of pasteurization is that treatment at this temperature reduces spoilage of food without affecting its taste. [Table 4.2](#) summarizes the applications of heat.

Filtration

Filtration methods can be used with both liquid and air. **Filtration** of liquids is accomplished through the use of thin membrane filters composed of plastic polymers or cellulose esters containing pores of a certain size. The liquid is pulled (vacuum) or pushed (pressure) through the filter matrix. Organisms larger than the size of the pores are retained. Filters with various pore sizes are available. Most bacteria, yeasts, and molds are retained by pore sizes of 0.45

and 0.80 µm; however, this pore size may allow passage of *Pseudomonas*-like organisms and mycoplasma; therefore a 0.22-µm size is available for critical sterilizing (e.g., parenteral solutions). Membranes with pore sizes of 0.01 µm are capable of retaining some viruses. The most common application of filtration is in the sterilization of heat-sensitive solutions, such as parenteral solutions, vaccines, and antimicrobial solutions. Filtration of air is accomplished with the use of high-efficiency particulate air (HEPA) filters. HEPA filters are able to remove microorganisms larger than 0.3 µm and are used in laboratory hoods and in rooms of immunocompromised patients.

Radiation

Radiation may be used in two forms: ionizing and non-ionizing. Ionizing radiation, in the form of gamma rays or electron beams, is of short wavelength and high energy. Ionizing radiation breaks chemical bonds and forms ions damaging and inactivating vital molecules. This method of sterilization is used by the medical field for the sterilization of heat-sensitive disposable supplies such as syringes, catheters, and gloves. Nonionizing radiation in the form of ultraviolet rays is of long wavelength and low energy. It damages deoxyribonucleic acid (DNA) by forming thymine and cytosine dimers. Because of its poor penetrability, usefulness is limited. It can be used to disinfect surfaces, although the parameters (distance to surface, potential microorganisms to be destroyed) under which it is to be used must be determined.

Chemical methods

Just as physical methods are used mainly to achieve sterilization, chemical agents are used mainly as disinfectants. However, some chemical agents may be used for sterilization. These are known as *chemosterilizers*. All disinfectants are regulated by the **Environmental Protection Agency** (EPA). Agents that are classified as *sterilants* are regulated by the **Food and Drug Administration** (FDA) when they are to be used to sterilize devices that will come in contact with patients. Chemical agents exert their killing effect by the following mechanisms:

- Reaction with components of the cytoplasmic membrane
- Denaturation of cellular proteins
- Reaction with the thiol (–SH) groups of enzymes
- Damage of RNA and DNA

It is important to remember that agents can exert one or a combination of actions on microorganisms. Damage to the integrity of the cytoplasmic membrane causes the cytoplasm and its contents to leak out, resulting in cell death. Denaturation of proteins effectively disrupts the metabolism of the cells. Some agents specifically react with the thiol (–SH) groups of enzymes, inactivating them. Thiol groups occur usually in the amino acid cysteine. Finally, damage to RNA and DNA inhibits the replication of the organism or gene expression. For ease of discussion, the chemical agents are grouped on the basis of chemical composition. [Table 4.3](#) summarizes the applications of chemicals commonly used as disinfectants and antiseptics.

Table 4.2 Control of microorganisms using heat methods

Method	Temperature (°C)	Time required	Applications
Boiling water (steam)	100	15 minutes	Kills microbial vegetative forms; endospores survive
Autoclave (steam under pressure)	121.6	15 minutes at 15 psi	Sterilizes and kills endospores
Pasteurization			
Batch method	63	30 minutes	Disinfects and kills milk borne pathogens and vegetative forms; endospores survive
Flash method	72	15 seconds	Same, but shorter time at higher temperature
Oven (dry heat)	160–180	1.5–3 hours	Sterilizes; keeps materials dry

Psi, Pounds per square inch.

Modified from VanDemark, P. J., & Batzing B. L. (1987). *The microbes: an introduction to their nature and importance*. Redwood City, CA: Benjamin-Cummings.

Table 4.3 Chemical agents commonly used as disinfectants and antiseptics

Type	Agent(s)	Action(s)	Applications and precautions
Alcohols (60%–90%)	Ethanol, isopropanol, benzyl alcohol	Denature proteins; make lipids soluble	Skin antiseptics
Aldehydes (in solution)	Formaldehyde (8%), glutaraldehyde (2%)	React with NH_2 , $-\text{SH}$, and $-\text{COOH}$ groups	Disinfectants; kill endospores; toxic to humans
Halogens	Tincture of iodine (2% in 70% alcohol)	Inactivates proteins	Skin antiseptics
	Chlorine and chlorine compounds	React with water to form hypochlorous acid (HClO); oxidizing agents	Used to disinfect drinking water and swimming pools; surface disinfectants
Detergents	Quaternary ammonium compounds	Disrupt cell membranes	Skin antiseptics; disinfectants
Phenolics	Phenol, carbolic acid, Lysol, hexachlorophene	Denature proteins; disrupt cell membranes	Disinfectants at high concentrations; used in soaps at low concentrations
Gases	Ethylene oxide	Alkylating agent	Sterilization of heat-sensitive objects

Modified from VanDemark, P. J., & Batzing B. L. (1987). *The microbes: an introduction to their nature and importance*. Redwood City, CA: Benjamin-Cummings.

Disinfectants versus antiseptics

The **germ theory of disease** was one of the most important contributions by microbiologists to the general welfare of the worldwide population. The medical community gradually grew aware of the problem of nosocomial (hospital-acquired) infections and the need to practice asepsis to prevent the contamination of wounds, dressings, and surgical instruments. The germ theory of disease also contributed to the development of antimicrobial chemotherapeutics.

Ignaz Semmelweis (1816–1865) and Joseph Lister (1827–1912) are considered to be important pioneers for the promotion of asepsis. More than 100 years ago, Semmelweis demonstrated that routine handwashing can prevent the spread of disease. Semmelweis worked in a hospital in Vienna where maternity patients were dying at an alarming rate. Most of the maternity patients who died had been treated by medical students who worked on cadavers during an anatomy class before beginning their rounds in the maternity ward. Because the students did not wash their hands between touching the dead and the living (handwashing was an unrecognized hygienic practice at the time), pathogenic bacteria from the cadavers were transmitted by the hands of the students to the mothers. The result was a death rate five times higher for mothers who delivered in the hospital in contrast with the mothers who delivered at home. Of women who delivered their babies in hospitals, 25% died of childbed fever (puerperal sepsis), later found to be caused by infection with *Streptococcus pyogenes*. In an experiment considered quaint at best by his colleagues, Semmelweis insisted that his students wash their hands before treating the mothers; deaths on the maternity ward were reduced fivefold. Despite these remarkable results, Semmelweis's colleagues greeted his findings with hostility, in part because of the results implying that physicians were unclean. Because of this hostility, he eventually resigned his position. Later in another maternity clinic, he had similar dramatic results when handwashing was implemented. Ironically, Semmelweis died in 1865 of infection with *S. pyogenes*, with his views still largely ridiculed.

After the death of Semmelweis, Lister, an academic surgeon, benefited by reading Pasteur's works about bacteria

as causes of infection before he ventured into studies of antiseptics. In 1867, Lister introduced handwashing and the use of phenol as an antimicrobial agent for surgical wound dressings to British surgery. His principles were gradually, although reluctantly, adopted in Britain, and the mortality rate for amputation decreased from 45% to 15%. The Listerian technique was approved in the United States 20 years after Semmelweis's initial publications at the first official meeting of the American Surgical Association in 1883. This was the beginning of infection control. Health care workers' hands are frequently contaminated by direct contact while caring for a patient or by indirect contact while touching a contaminated surface or device.

Alcohols

The two most effective alcohols used in hospitals for disinfection purposes are ethyl alcohol and isopropyl alcohol. Alcohols have excellent in vitro bactericidal activity against most gram-positive and gram-negative bacteria. They also kill *Mycobacterium tuberculosis* and various fungi, and they inactivate certain enveloped viruses. However, they are not sporicidal and have poor activity against nonenveloped viruses. Because alcohols are not sporicidal, alcohol may actually be contaminated with spores. Any solution of an alcohol that is used as an antiseptic or disinfectant should be filtered through a 0.22- μm filter to remove spores that may be present. In addition, because alcohols are not sporicidal, when alcohol is used to saturate cotton balls to be used to prepare the skin for blood collection or inoculation, the cotton balls should be sterile. Today, alcohols used as an antiseptic are sold as sterile, individually wrapped pads.

Alcohols are inactivated by the presence of organic material. Because their action is greatly reduced in concentrations less than 50%, alcohols should be used in concentrations between 60% and 90%. For alcohols to be effective, they must be given time to evaporate from the surface to which they were applied. Alcohols inactivate microorganisms by denaturing proteins, dehydrating cells, and dissolving lipids. Alcohols are used as antiseptics and disinfectants. They are used to disinfect laboratory surfaces and gloved hands, as well as skin surface before venipuncture, injection, or

inserting an intravenous needle. They may be used as a housekeeping disinfectant for damp-dusting furniture and lights or wiping electrical cords without leaving a residue on treated surfaces. They are nonstaining and can disinfect semi-critical instruments. Alcohols are flammable, so they should not be used in the presence of ignition sources such as open flames or incinerators.

The 2017 final rule for **health care antiseptic drug products** defers ethanol (60% to 95%) from inclusion in the final rulemaking to allow more time for completion of studies necessary to fill the data gaps needed for health care personnel handwash, surgical hand scrub, and patient preoperative skin preparation (for preparation of the skin before injection). After reviewing currently available scientific evidence, the FDA tentatively determined that there are important scientific data gaps for health care antiseptic products marketed under the previous 1994 tentative final monograph (TFM) proposed rule to support the products' effectiveness at reducing infections and meet safety requirements. The 2015 proposed rule states that more extensive data than previously proposed in the 1994 TFM are necessary to demonstrate that **over-the-counter (OTC)** monograph topical antiseptics used in the health care setting are **generally recognized as safe and effective** (GRASE). At the present time, the FDA is evaluating additional safety and efficacy of alcohols for use as health care antiseptics.

Aldehydes

Formaldehyde

Formaldehyde is generally used as formalin, a 37% aqueous solution, or formaldehyde gas. Formaldehyde gas is often used to disinfect **biological safety cabinets** (BSCs). This type of procedure should be performed by professionals. Although formalin can be used as a chemosterilizer in high concentrations, its usefulness is limited by its irritability factor and its potential carcinogenicity. Formaldehyde is a carcinogen, and the U.S. Occupational Safety and Health Administration (OSHA) has set worker exposure limits. It is not recommended that formaldehyde in any form be used as a disinfectant or sterilant on a routine basis. *M. tuberculosis* has been known to survive for many years in tissue fixed in formaldehyde.

Glutaraldehyde

Glutaraldehyde, classified as a high-level disinfectant, is a saturated five-carbon dialdehyde that has broad-spectrum activity and rapid killing action and remains active in the presence of organic matter. Glutaraldehyde is extremely susceptible to pH changes and is active only in an alkaline environment. When used as a 2% solution, it is germicidal in approximately 10 minutes and sporicidal in 3 to 10 hours. Its killing activity is caused by inactivation of DNA, RNA, and proteins through alkylation of sulfhydryl and amino groups. Even though glutaraldehyde is not inactivated by organic material, it does not penetrate organic material well. Therefore objects coated with organic material should be cleaned before glutaraldehyde is used. Glutaraldehyde solutions can be reused; however, a decrease in the activity of the glutaraldehyde may be seen as a result of accumulation of organic material, dilution, and change in the pH of the solution. Because it does not corrode

lenses, metal, or rubber, it is the sterilizer of choice for medical equipment that is not heat-stable and cannot be autoclaved and for material that cannot be sterilized with gas. It is safe, for most plastic and rubber items, such as items used for administering anesthetic agents or respiratory therapy.

Glutaraldehyde is bactericidal, pseudomonacidal, fungicidal, and virucidal (against human immunodeficiency virus [HIV] and hepatitis B virus [HBV]) with a minimum of 10 minutes exposure at a temperature between 20° and 30°C. It is also tuberculocidal. Variations in formulations of products available affect the exposure time and temperature of the solution, especially after reuse. A 2% solution at 25° to 30°C may be 100% tuberculocidal. Users should follow the label instructions of the manufacturer. Most of the products labeled as *cold sterilants* are sporicidal in a minimum of 10 hours exposure at room temperature.

Halogens

Iodophors

Iodine can be used in one of two forms: tincture or iodophor. Tinctures are alcohol and iodine solutions, used mainly as antiseptics. An iodophor is a combination of iodine and a neutral polymer carrier that increases the solubility of the agent. This combination allows the slow release of iodine. Iodophors must be diluted properly for them to be effective. Improperly diluted iodophors may not kill microorganisms because of the lack of free iodine in solution. Iodophors have the added advantage of being less irritating, nonstaining, and more stable than iodine in its pure form. Iodophors may be used as antiseptics or disinfectants, depending on the concentration of free iodine. The best known iodophor is povidone-iodine (Betadine), which is mainly used as an antiseptic. Povidone-iodine provides slow and continuous release of free iodine. Free iodine degrades microbial cell walls and cytoplasm, denatures enzymes, and coagulates chromosomal material.

Iodophors are commonly used as skin preparation agents for sites where blood is to be drawn for blood cultures. When iodophors are used for this purpose, it is critical that there is the proper amount of contact time, which is generally more than 30 seconds. All iodine tinctures and iodophors must be completely removed from the skin to avoid irritation. Iodophors are used only to disinfect because they are not sporicidal. Their bactericidal action is caused by the oxidative effects of molecular iodine and hypoiodic acid, both of which are found in solution. The FDA has deferred povidone-iodine 5% to 10% from inclusion in the final rulemaking to allow more time for completion of studies necessary to fill the data gaps for health care personnel handwash, surgical hand scrub, and patient preoperative skin preparation. At the present time, the FDA is evaluating safety and efficacy data of iodophors for use as health care antiseptics.

Chlorine and chlorine compounds

Chlorine and chlorine compounds are some of the oldest and most commonly used disinfectants. They are usually used in the form of hypochlorite, such as the liquid sodium hypochlorite (household bleach) and solid calcium hypochlorite.

Their killing activity is based on the oxidative effects of hypochlorous acid, which is formed when chloride ions are dissolved in water. Hypochlorites are inexpensive and have a broad spectrum of activity; however, they are not used as sterilants because of the long exposure time required for sporicidal action and their inactivation by organic matter. Hypochlorites are corrosive; therefore concentrated bleach solutions should not be used for disinfection. The activity of hypochlorite solutions is greatly influenced by the pH of the surrounding medium.

These solutions are commonly used as surface disinfectants (e.g., for tabletops). A solution containing 0.5% to 1% sodium hypochlorite is generally used for disinfection. Such solutions are generally stable for no longer than 30 days, with 50% of the original concentration of chlorine dissipating by 30 days. However, current practice recommends making a fresh dilution daily. As with the use of any disinfectant, proper contact time is critical for bleach solutions. Solutions should be allowed a contact time of at least 3 minutes, and longer if organic material is present. A 1:10 dilution of a 5.25% concentration of sodium hypochlorite is recommended by the Centers for Disease Control and Prevention (CDC) for cleaning blood spills. The most common use of chlorine is disinfection of water.

Detergents: quaternary ammonium compounds

Quaternary ammonium compounds are derived by substitution of the four-valence ammonium ion with alkyl halides. They are cationic, surface-active agents (surfactants) that work by reducing the surface tension of molecules in a liquid. Their effectiveness is reduced by hard water and soap, and they are inactivated by excess organic matter. Their action is mediated through disruption of the cellular membrane, resulting in leakage of cell contents. Certain bacteria, particularly gram-negative bacteria such as *Pseudomonas aeruginosa*, are intrinsically resistant to quaternary ammonium compounds. *Pseudomonas* spp. growing in ammonium acetate-containing quaternary ammonium compounds and disease outbreaks associated with contaminated quaternary ammonium compounds have been reported. Because they are not sporicidal or tuberculocidal, the use of quaternary ammonium compounds is limited to disinfection of noncritical surfaces such as tabletops and floors.

Phenolics

Phenolics are molecules of phenol (carbolic acid) that have been chemically substituted, typically by halogens or alkyl, phenyl, or benzyl groups. These groups reduce the toxicity of phenol and increase its effectiveness. The most common phenolics are *ortho*-phenylphenol and *ortho*-benzyl-*para*-chlorophenol. Phenolics have a fairly broad spectrum of activity but are not sporicidal. The addition of detergents to the phenol formulation makes products that clean and disinfect in one step. They are stable, biodegradable, and relatively active in the presence of organic material. Their mechanism of inactivation is disruption of cell walls, resulting in precipitation of proteins. At lower concentrations, phenolics are able to disrupt enzyme systems. Their main use is in the disinfection

of hospital, institutional, and household environments. They are also commonly found in germicidal soaps.

Chlorhexidine gluconate

Chlorhexidine gluconate (CHG) has been used for more than 30 years in the hospital setting. In 1976, the FDA granted approval of CHG for use as a topical antiseptic on the basis of its high level of antimicrobial activity, low toxicity, and strong affinity for binding to the skin and mucous membranes. CHG was not an OTC drug monograph active ingredient at that time. CHG disrupts the microbial cell membrane and precipitates the cell contents. CHG is broad spectrum, being active against gram-positive and gram-negative bacteria. It has less activity against fungi and tubercle bacilli. CHG is bacteriostatic (inhibits bacterial growth) at low concentration and bactericidal (kills bacteria) at high concentration. CHG is inactive against bacterial spores except at elevated temperatures. Lipid-enveloped viruses (e.g., herpesvirus, HIV, influenza virus, cytomegalovirus) are rapidly inactivated. Nonenveloped viruses (e.g., rotavirus, adenovirus, enteroviruses) are not inactivated by CHG.

Numerous studies indicate that CHG is safe and nontoxic. It is not absorbed through the skin and has a low skin-irritancy potential. However, severe skin reactions can occur in infants younger than 2 months of age. The potential for allergic contact sensitization and photosensitization is reported to be minimal. However, CHG should not come into contact with the eyes, the middle ear, or meninges. Although CHG is not as rapidly effective as the alcohols, a major attribute of CHG is its persistence in that it binds to the skin and remains active for at least 6 hours. It is not significantly affected by organic matter such as blood and is pH-dependent—hence the formulation significantly affects activity. The optimum pH range of 5.5 to 7.0 corresponds to the pH of body surfaces and tissues.

CHG is used extensively for disinfection of the hands of surgical personnel and provides whole-body disinfection of patients undergoing surgery. Low-concentration (0.5% to 1%) CHG is added to alcohol-based preparations to provide greater residual activity than alcohol alone. The immediate bactericidal action of CHG surpasses that of antiseptic preparations containing povidone-iodine, triclosan, hexachlorophene, or chloroxylenol. Its persistence, which prevents regrowth of microorganisms on the skin, is comparable to that of hexachlorophene or triclosan. CHG has a broader spectrum of activity than the others, especially against gram-negative bacteria.

Hexachlorophene

Hexachlorophene is primarily effective against gram-positive bacteria. It is a chlorinated bisphenol that interrupts bacterial electron transport, inhibits membrane-bound enzymes at low concentrations, and ruptures bacterial membranes at high concentrations. Gram-positive bacteria are killed by 3% hexachlorophene within 15 to 30 seconds, but a longer time is needed for gram-negative bacteria. Hexachlorophene has residual activity for several hours after application and has a cumulative effect after multiple uses. Hexachlorophene has been associated with severe toxic effects, including death. It can be absorbed through damaged skin of adults and the skin of premature infants. The FDA classified 3% hexachlorophene

to be available only by prescription and designated it as unsafe for OTC distribution. Hexachlorophene is indicated to control outbreaks of gram-positive infections when other infection-control procedures have been unsuccessful. Hexachlorophene should be used only as long as necessary for infection control.

Chloroxylenol

Chloroxylenol (parachlorometaxylenol [PCMX]) is a halogen-substituted phenolic compound that has been used in the United States since the 1940s. PCMX at concentrations of 0.5% to 4% acts by microbial cell wall disruption and enzyme inactivation. PCMX has good activity against gram-positive bacteria, but it is less active against gram-negative bacteria, *M. tuberculosis*, fungi, and viruses. The antimicrobial activity of PCMX is unaffected by organic materials such as blood or sputum, but it is neutralized by nonionic surfactants and polyethylene glycol. It is considered intermediate-acting to slow-acting and has minimal **persistent** effect of more than a few hours. PCMX has low antimicrobial efficacy compared with iodines, iodophors, and CHG in reducing skin biota. The FDA has deferred PCMX (0.24% to 3.75%) from inclusion in the final rulemaking to allow more time for completion of studies necessary to fill the data gaps for health care personnel handwash. The FDA is currently evaluating additional safety and efficacy of PCMX for use as a health care antiseptic under the OTC drug review.

Triclosan

Triclosan is a diphenyl ether that disrupts the cell wall. The reaction time is intermediate, and the persistence is excellent. It has good activity against gram-positive bacteria, gram-negative bacteria, and viruses. It has fair activity against *M. tuberculosis* but poor activity against fungi. Triclosan is not significantly affected by organic matter such as blood, but it is affected by pH and the presence of surfactants and emollients, and formulation significantly affects activity. Triclosan can be absorbed through intact skin. Some short-term animal studies have shown that exposure to high doses of triclosan is associated with a decrease in the levels of some thyroid hormones. The FDA currently does not know the significance of these findings to human health. Other studies have raised the possibility that exposure to triclosan contributes to making bacteria resistant to antimicrobial agents. The FDA currently does not have enough information available to assess the level of risk that triclosan poses for the development of antimicrobial resistance. The FDA published a final rule for consumer antiseptic hand and body washes and health care antiseptics containing the majority of the antibacterial active ingredients, including triclosan and triclocarban, that they will no longer be able to be marketed.

Manufacturers have not proven that triclosan is safe for daily use over a long period. Additionally, manufacturers have not shown that this ingredient is any more effective than plain soap and water in preventing illness and the spread of certain infections. Triclosan has been added to many consumer products, including clothing, kitchenware, furniture, toothpaste, and toys to prevent bacterial contamination. The EPA regulates the use of triclosan in these products and is presently reevaluating its assessment of the effects of triclosan when used in these products.

Heavy metals

Disinfectants containing heavy metals are rarely used in clinical applications. They have been replaced by safer and more effective compounds. Heavy metal disinfectants are slowly bactericidal; their action is primarily bacteriostatic. Because of the toxic effects of mercuric chloride and other mercury compounds, their use as disinfectants has declined, and they are used mainly as preservatives for paint. Silver nitrate (1% eye drop solution) had been used as a prophylactic treatment to prevent gonococcal (*Neisseria gonorrhoeae*) conjunctivitis in newborns. It has been largely replaced by erythromycin drops. Copper and copper alloys (e.g., brass, bronze) are the first solid surface materials ever to receive approval by the EPA to be considered antimicrobial for health care use. They are being evaluated for use lining rails and door handles in health care facilities to mitigate the spread of microorganisms.

Gases

Ethylene oxide

Ethylene oxide is the gas most commonly used for sterilization. Because it is explosive in its pure form, it is mixed with nitrogen or carbon dioxide before use. Factors such as temperature, time, and relative humidity are extremely important in determining the effectiveness of gas sterilization. The recommended concentration is 450 to 700 mg of ethylene oxide per liter of chamber space at 55° to 60°C for 2 hours. A relative humidity of 30% is optimal for the destruction of spores. The killing mechanism of ethylene oxide is the alkylation of nucleic acids in the spore and vegetative cell. Gas sterilization is widely used in hospitals for materials that cannot withstand steam sterilization. This method is also used by the manufacturing industry for the sterilization of low-cost thermoplastic products. However, its use has declined in the last few decades because of health concerns and time needed for sterilization.

Hydrogen peroxide

Vaporized hydrogen peroxide (H_2O_2) is primarily used as a sterilant in the pharmaceutical and medical device manufacturing industries. It is active against all vegetative microorganisms, bacterial endospores, and fungal spores. In a 3% to 6% liquid form, it can be used as an antiseptic with an intermediate to high activity level. Hydrogen peroxide can be inactivated by bacterial peroxidases and catalases.

Peracetic acid

Peracetic acid is used as a gaseous sterilant primarily in the pharmaceutical and medical device manufacturing industries. It is active against all vegetative microorganisms and bacterial and fungal spores.

Hydrogen peroxide and peracetic acid

The combination of H_2O_2 and peracetic acid vapors is used in the pharmaceutical and medical device manufacturing industries. Similar to each of its individual components, the combination of H_2O_2 and peracetic acid is active against all

vegetative forms of microorganisms and bacterial and fungal spores. The major advantage to the use of the combination of H_2O_2 and peracetic acid over each individual component is a shorter contact time. The activity against prions of the combination of H_2O_2 and peracetic acid as well as each of the individual components is not fully known.

EPA regulations on chemical surface disinfectants

The Antimicrobial Division of the EPA regulates the registration on the use, sale, and distribution of antimicrobial pesticide products for certain inanimate, hard nonporous surfaces or incorporation of antimicrobial pesticide products into substances under the pesticide law—the Federal Insecticide, Fungicide, and Rodenticide Act. An EPA registration number is granted only when the requirements of laboratory test data, toxicity data, product formula, and label copy are approved. The label of a disinfectant that is effective against a specific major group of microorganisms only (e.g., gram positive or gram negative) must specify the major group against which it is effective. Label claims of effectiveness as a “general disinfectant” or representations that the product is effective against a broad spectrum of microorganisms are acceptable if the product is effective against gram-positive and gram-negative bacteria. Label claims for use of disinfectants in hospital or medical environments are acceptable only for products that are effective as general or broad-spectrum disinfectants as well as disinfectants against the healthcare-associated bacterial pathogen *P. aeruginosa*. The disinfectant label should indicate several highlighted points important in selecting the appropriate agents for the designated use (Box 4.1).

BOX 4.1 Type of information to review on a disinfectant label

Front panel

- Product name, brand, or trademark
- Ingredient statement (concentration or strength)
- “Keep Out of Reach of Children”
- EPA registration number and establishment number

Back panel

FDA regulations on chemical skin antiseptics

When developing an antiseptic drug product, a manufacturer can pursue two options: the **new drug application (NDA)** process or the OTC drug review known as the *monograph system*. NDAs are defined by law as being recognized as safe and effective. A new chemical entity never before marketed in the United States would be classified as a new drug and, in most cases, initially approved for prescription use only. The approved NDA is manufacturer-specific and allows only that particular sponsor to market the product. Other manufacturers wanting to market a similar product would also need to seek FDA approval through an NDA. The FDA considers a drug safe enough to approve when the benefits outweigh the risks. This risk-to-benefit assessment is critical in the drug-approval process.

OTC drugs are defined as GRASE for their intended use as long as they are neither misbranded nor marketed using false or misleading statements. In March 2020, the Coronavirus Aid, Relief, and Economic Security Act (the CARES Act) ushered in a wave of reforms to modernize the regulation of OTC drugs in the United States. Many of the new provisions had immediate effect. For example, replacement of the notice-and-comment rulemaking process for OTC drug monograph or Tentative Monograph are deemed GRASE under the CARES Act. These existing monographs, with some caveats, are being converted into final administrative orders. Administrative orders allow for faster agency decisions as the process can be run through the FDA instead of being required to go through the rulemaking process with issuance of a final rule (as required by the old OTC drug review process). The new system is meant to help streamline the process and provide a more efficient and effective review.

A manufacturer desiring to market a monographed (therapeutic classes of ingredients that are GRASE) drug does not need to seek clearance from the FDA before marketing the drug. In this case, marketing is not exclusive, and all data and information supporting GRASE status are publicly available. Monographs mainly address active ingredients in the product, and final formulations are not subject to monograph specifications in most cases. Manufacturers are free to include any inactive ingredients that serve a pharmaceutical purpose as long as those ingredients are considered safe and do not interfere with product effectiveness or required final product testing. In some instances, although the product may contain GRASE ingredients, the final formulation may need to meet a monograph testing procedure. An example would be the antiseptic drug products that are for **health care personnel handwash, surgical hand scrub, and patient preoperative skin preparation**. Table 4.4 lists terms and definitions frequently used for topical antiseptics in health care settings. These products are required to meet in vivo and in vitro efficacy testing requirements to ensure that the formulated products are effective as an antiseptic. Inactive ingredients and emollients can inhibit the antiseptic action when included in the products; therefore testing must be performed to show effectiveness.

Table 4.4 Food and Drug Administration product categories of topical antiseptics

Category	Definition
Antiseptic drug	Representative of a drug, in its labeling, as an antiseptic shall be considered to be representation that it is a germicide, except in the case of a drug purporting to be, or represented as, an antiseptic for inhibitory use as a wet dressing, ointment, dusting powder, or such other use as involves prolonged contact with the body
Broad-spectrum activity	Properly formulated drug product, containing an ingredient included in the monograph, that possesses in vitro activity against the microorganisms listed in §333.470(a)(1)(ii), as demonstrated by in vitro minimum inhibitory concentration determinations conducted according to methodology established in §333.470(a)(1)(ii)
Health care antiseptic drug product	Antiseptic-containing drug product applied topically to the skin to help prevent infection or help prevent cross contamination
Antiseptic handwash or health care personnel handwash drug product	Antiseptic-containing preparation designed for frequent use; it reduces the number of transient microorganisms on intact skin to an initial baseline level after adequate washing, rinsing, and drying; it is broad-spectrum, fast-acting, and, if possible, persistent
Surgical hand scrub drug product	Antiseptic-containing preparation that significantly reduces the number of microorganisms on intact skin; it is broad-spectrum, fast-acting, and persistent
Patient preoperative skin-preparation drug product	Fast-acting, broad-spectrum, and persistent antiseptic-containing preparation that significantly reduces the number of microorganisms on intact skin
From Federal Register on the tentative final monograph for health-care topical antiseptic drug products (June 17, 1994, 59 FR 31402).	

Hygienic handwashing and waterless handrubs

The main goal of handwashing is to eliminate **transient biota**. Transient biota is contracted from the environment or from other people. In most cases, these organisms are not part of the established normal biota.

Case check 4.1

The Case in Point exemplifies the significance of handwashing in the prevention of disease and pathogen transmission. Routine handwashing in health care settings is performed in the following situations:

- Removing physical dirt (including blood, excretions, secretions, or discharge from lesions)
- Before and after routine patient contact
- After contact with infected or colonized patients or their immediate surroundings
- In high-risk units such as intensive care and burn units
- On entering protective isolation units and leaving source isolation units
- Before antiseptic procedures (e.g., dressing techniques, minor invasive procedures)

For example, the health care worker in the Case in Point may acquire infectious agents, including methicillin-resistant *Staphylococcus aureus* (MRSA) and coronavirus-2 (CoV-2), during direct contact with patients or contaminated surfaces (e.g., doorknobs). Hands should always be washed immediately after touching an object. Although the health care worker's hands appeared to be clean, her hands harbored many bacteria and infectious microorganisms after having contact with the contaminated doorknob. She should have either washed her hands or used hand sanitizer as soon as she entered the room.

According to the CDC, washing hands with plain soap and water is the best way to avoid being infected and to prevent

the spread of infections. If soap and water are not available, the CDC recommends using an alcohol-based hand sanitizer that contains at least 60% alcohol to reduce the number of organisms on hands. However, hand sanitizers do not eliminate all types of bacteria, are not as effective when hands are visibly dirty or greasy, and may not remove harmful chemicals. Hand sanitizers are an easy, quick alternative when handwashing with plain soap and water is not convenient or possible. Hand hygiene should be a topic of conversation between the health care provider and the patient. Health care providers should not hesitate in discussing how and why they cleanse their hands before, after, and sometimes during patient care, and they should inform the patient that it is okay to ask about hand hygiene. Although transient organisms are easily removed from the upper layer of the skin along with dirt particles and oil, they may become part of the **resident biota** of individuals. Interventions against the bacterial load of the hands should balance two goals: (1) protecting the skin with its resident biota and (2) killing the transient biota. Intact skin on health care workers' hands helps protect both patients and health care workers from getting or transmitting healthcare-associated infections.

The FDA requires that all antiseptic handwashing and handrubbing products used in the hospital setting reduce the number of sampled test bacteria by a superiority margin (compared with a negative control) of $1.2 \log_{10}$ for handwash and $1.5 \log_{10}$ for handrub on each hand within 5 minutes after the first wash/rub application. The technique involves treating the hands with the antiseptic product according to the manufacturer's instructions for the specified time. The lower third of the forearm is also washed. After completion of the wash, hands and forearms are rinsed under tap water ($40^\circ\text{C} \pm 2^\circ\text{C}$) and dried thoroughly with disposable or sterilized towels.

Waterless handrubs (e.g., alcohol handrubs)—either liquid or gel—are used for hygienic hand antiseptics. They also can be used as an alternative to routine handwashing when there is no visible soiling and for patient contact. They are often more convenient than handwashing and can be particularly

useful if sinks are not readily available. Dispensers for alcohol handrubs can be placed next to sinks and beside each bed or carried by health care providers. The technique involves rubbing small portions (3 to 5 mL) of a **fast-acting antiseptic**, usually an alcoholic preparation, into the hands and rubbing until dry or for a preset duration recommended by the manufacturer. All areas of the hands must be covered completely with the antiseptic, including the subungual spaces of the fingers.

Surgical hand scrub and waterless surgical handrubs

The objective of the surgical hand scrub and waterless surgical handrubs is to eliminate transient biota and most of the resident biota. Resident biota can be persistently isolated from the hands of most people. These organisms include coagulase-negative staphylococci, *Corynebacterium* spp. (diphtheroids or coryneforms), *Propionibacterium* spp., *Cutibacterium*, and *Acinetobacter* spp.

The rationale is to limit bacterial exposure of the surgeon's hands in case the surgical glove is punctured or torn. Tiny holes are observed in 30% or more of surgeons' gloves after an operation, even when high-quality gloves are used. A surgical hand scrub drug product is defined as an antiseptic containing a preparation that significantly reduces the number of microorganisms on intact skin; it is broad-spectrum, fast-acting, and persistent. The FDA requires that the product reduce on the first wash/rub the number of bacteria by a superiority margin of $0.5 \log_{10}$ for hand scrub and $1.5 \log_{10}$ for handrub on each hand within 1 minute after application and that the count on each hand does not subsequently exceed the baseline within 6 hours after product use. Surgical hand scrub procedures are performed according to the manufacturer's instructions, but for no longer than 5 minutes. They offer the advantage of cleansing and disinfecting the hands at the same time.

Surgical handrubs, alcohol solutions (60% to 70% ethyl alcohol or propyl alcohol) with an emollient and with or without an added antiseptic as recommended for hygienic waterless handrubs, are used, but larger volumes and longer exposure times are needed than for hygienic waterless handrubs. Surgical handrub application technique is accomplished by pouring a specified amount of antiseptic into the cupped dry hands and rubbing vigorously all over the hands and forearms, which must be kept wet with the handrub solution for the period of 3 to 5 minutes by adding additional portions as necessary and continuing to rub. Before the application of an alcohol, the hands must be dry, and the alcohol must have completely evaporated before donning gloves.

Presurgical skin disinfection

To be effective, preoperative skin preparation formulations must degerm an intended surgical site rapidly as well as provide a high level of bacterial inactivation and persistent antimicrobial activity, up to 6 hours after preparing the skin. A patient preoperative skin preparation drug product is defined as a fast-acting, broad-spectrum, and persistent antiseptic-containing preparation that significantly reduces

the number of microorganisms on intact skin. Similar to the surgeon's hands, the patient's operation site requires surgical disinfection, directed against resident as well as transient biota, and it often requires maximum disinfection in a single treatment, without the benefit from progressive effects of repeated application.

The FDA requires that the product reduce the number of bacteria by a superiority margin of $1.2 \log_{10}$ per square centimeter on an abdomen and groin test site within 30 seconds or 10 minutes after product use and that the bacterial count for each test site does not exceed the baseline within 6 hours after product use. For preinjection sites, the product must reduce the number of bacteria by a superiority margin (compared with a negative control) of $1.2 \log_{10}$ per square centimeter on a dry skin test site within 30 seconds after product use. It has long been debated whether or not a preoperative skin preparation is adequate in degerming the skin before making a surgical incision. Many surgeons recognize this problem, and to promote greater degerming of the surgical site area, patients are requested to wash the area daily, or more often, before surgery. The intent is to reduce the microbial population at the surgical site area so the region is prepared before surgery. The organisms, then being few in number, would be virtually totally removed from the skin.

Microbiology laboratory safety

Case in point

A 35-year-old infectious disease specialist complains of experiencing fever, chills, myalgia, and severe headache for the past several days. The patient has been otherwise healthy until 2 weeks ago, when he began to experience fatigue and slightly swollen cervical lymph nodes. The patient recalls that he demonstrated to his medical students and residents a culture of *Brucella melitensis* isolated from a patient's blood sample. While handling the Petri dish without gloves, he picked up the telephone to answer a page. He then touched his mustache while talking on the telephone, as he habitually does when he speaks.

Issues to consider

After reading the patient's case history, consider:

- Potential risks to which laboratory scientists are exposed while working in the microbiology laboratory
- Exposure control plan to minimize the risks
- Laboratory safety guidelines to protect laboratory personnel

While laboratory safety procedures have improved greatly over the last few decades, safety in the clinical laboratory is a major concern, and work practices must be continually reevaluated. Studies have shown that laboratorians are at increased risk of infections compared with the general population. Laboratory exposures do occur, and often they cannot be traced back to a specific event. In 2012, the CDC published "Guidelines for Safe Work Practices in Human and Animal Medical Diagnostic Laboratories." This report was developed to improve safety in the laboratory by increasing safe practices, to encourage laboratorians to consider safety issues, and to foster a culture of safety. Safety in the clinical laboratory

encompasses biological, chemical, electrical, radioactive, and fire hazard protection.

General laboratory safety

Safety in the clinical laboratory is the responsibility of the institution, laboratory directors, laboratory managers, and laboratory employees. Laboratory employees must be provided with a safe work environment and necessary **personal protective equipment (PPE)**. OSHA defines PPE as specialized clothing or equipment that is worn by an employee for protection. Laboratory directors, managers, and employees must know the current safety regulations; safety procedure manuals must be provided; and training in safe laboratory practices must occur on an annual basis through in-service education and should be the duty of an assigned safety officer. Although the provision of a safe work environment is ultimately the employer's responsibility, it cannot be achieved without the commitment of all persons in that environment to practice safe techniques for their own and their coworkers' protection.

Case check 4.2

The Case in Point at the beginning of this section illustrates the importance of a safety program for the clinical laboratory. Safety in the laboratory is the responsibility of all laboratory personnel. Everyone who enters the laboratory must also observe the safety guidelines to ensure proper protection and reduce risk of exposure to potentially hazardous biological agents.

Safety program for the clinical laboratory

The comprehensive safety program for the clinical laboratory must fulfill the following:

- Address biological hazards by performing biological risk assessments and developing safety procedures for working with these hazards.
- Describe the safe handling, storage, and disposal of chemicals and radioactive substances.
- Clearly outline the laboratory or hospital policies for correct procedures in the event of fire, natural disasters, and bomb threats.
- Perform initial safety training for all employees in all aspects of laboratory safety and update training annually.
- Teach correct techniques for lifting and moving heavy objects.

The safety program must be ongoing and consistent with current federal and state regulations. Most important, it must be presented in a way that encourages employees to incorporate the safety practices into their daily routines and take responsibility for keeping the work environment safe.

Occupational Safety and Health Administration

Laboratorians must always remember that they work in a hazardous environment. Hazards can be classified as biological, chemical, radiologic, or physical. Training programs are instituted in all of these areas for employees who encounter any of these hazards. It is imperative for

individuals to follow the rules that are set forth in the safety procedure manuals.

The mission of the OSHA is to protect workers within the United States. The clinical laboratory falls under these regulations. In 1991, the OSHA created and released the Bloodborne Pathogens Final Standard to protect health care workers. This standard was revised in 2001 in conformance with Public Law 106-430, the Needlestick Safety and Prevention Act.

Exposure control plan

The OSHA Bloodborne Pathogens Final Standard clearly states the safety requirements that the employer must have in place to protect employees from **bloodborne pathogens**. Employers are required to have an **exposure control plan**, which must be reviewed and updated annually. This plan must be available to all employees and should include the following:

- A determination of tasks and procedures that may result in an occupational hazard
- A plan to investigate all exposure incidents and a plan to prevent these from recurring
- Methods of compliance for standard precautions
- Engineering and work practice controls
- PPE required
- Guidelines for ensuring that the work site is maintained in a clean and sanitary manner
- Guidelines for the handling and disposal of regulated waste
- A training program for all employees

Standard precautions

In 1985, the CDC instituted safety guidelines for the handling of blood and body fluids. These guidelines, called *universal precautions*, were intended to protect hospital personnel from bloodborne infections. In 1996, these guidelines were updated and renamed. These new guidelines, **standard precautions**, are still in effect. These guidelines require that blood and body fluids from *all* patients be considered infectious and capable of transmitting disease. Blood and all body fluids, including secretions and excretions except sweat, regardless of whether visible blood is present, are considered infectious. Standard precautions also include nonintact skin and mucous membranes.

To ensure that the guidelines required in standard precautions are followed within the laboratory, engineering controls and work practice controls are instituted, and employers must provide PPE. Standard precautions address the following:

- *Handwashing* must be done after touching blood, body fluids, secretions, excretions, and any items considered contaminated. Hands must be washed after removal of gloves and between patients.
- *Gloves* should be worn when handling blood, body fluids, secretions, excretions, and any items considered contaminated. Clean gloves must be put on before touching mucous membranes and nonintact skin. Hands must be washed after removal of gloves.
- *Mask, eye protection, or face shield* must be worn anytime there is a potential for splashes or sprays of blood, body fluids, secretions, or excretions.

- *Laboratory coats* must be worn to protect skin and clothing when contact with blood, body fluids, secretions, or excretions could occur.
- *Appropriate sharps disposal* must be implemented with care to prevent injuries with sharps, needles, and scalpels. These devices must be placed in appropriate puncture-resistant containers after use.
- *Environmental control* must include procedures for routine care, cleaning, and disinfection of environmental surfaces.

Transmission-based precautions

The second set of precautions for the health care setting are called **transmission-based precautions**. Standard precautions are still followed, and transmission-based precautions are added precautions that are used when the patient is known or suspected to be infected or colonized with an infectious agent that requires extra measures to prevent spread or transmission of the agent. The categories of these precautions are contact precautions, droplet precautions, and airborne precautions. Contact precautions are used to stop the spread of infectious agents that can be transmitted through direct or indirect contact with the patient or with the patient's environment. Examples of these types of infectious agents are multidrug-resistant organisms such as vancomycin-resistant enterococci, MRSA, and *Clostridioides difficile*.

Droplet precautions are used to stop the spread of infectious agents that can be transmitted by close respiratory contact or by exposure of mucous membranes to respiratory secretions. Examples of infectious agents that can be transmitted by this route include *Neisseria meningitidis*, *Bordetella pertussis*, influenza virus, and CoV-2. The final category is airborne precautions. These precautions are used for infectious agents, such as *M. tuberculosis*, varicella-zoster virus, and rubeola virus, that can remain airborne and infectious over long distances. For further information on what safety procedures should be used for each category of precautions, refer to the 2007 (Updated 2019) *Guideline for Isolation Precautions: Preventing Transmission of Infectious Agents in Health care Settings* published by the CDC.

Engineering controls

Engineering controls are defined by the OSHA as controls that isolate or remove the hazard from the workplace. Examples of engineering controls include the use of closed tube sampling by laboratory equipment and the use of safety needles and single-use holders, eyewash stations, emergency showers, and plastic shield barriers. Ideally, laboratories should have negative air pressure, access to the laboratory should be limited, and there should be a plan to prevent insect infestation.

Work practice controls

Altering the manner in which a task is performed to reduce the likelihood of exposure to infectious agents is defined by the OSHA as **work practice controls**. Examples of work practice controls include the following:

- No mouth pipetting
- No eating, drinking, smoking, or applying cosmetics in the laboratory
- Disinfection of workstations at the end of each shift and after any spill of infectious material
- No recapping or breaking of contaminated needles
- Disposal of needles in an appropriate puncture-resistant container
- Procedures performed in a manner that minimizes splashing and the generation of air droplets
- Specimens transported by way of well-constructed containers with secure lids to prevent leakage of infectious materials
- Frequent handwashing

Personal protective equipment

PPE must be provided and maintained by the employer; examples include gloves, laboratory coats, masks, respirators, face shields, and safety glasses. For PPE to be protective and considered appropriate, blood and body fluids must not be able to penetrate the PPE material. The equipment must be accessible to the employee and must be worn whenever there is the potential for exposure to infectious material. It must be removed before leaving the work area and must be placed in an area designated for PPE. Gloves should be removed whenever they become contaminated, and disposable gloves should *never* be washed and reused. Hands must be washed after the removal of gloves.

PPE must fit properly to be the most effective. Respirators that are used for protection against airborne transmission of infectious agents must be fit-tested to ensure the protection of the worker. Fig. 4.3 illustrates goggles, masks, and laboratory garments appropriate for use in laboratory workstations.

Biological risk assessment

For an infection to occur, including an LAI, there must be a susceptible host, the infectious agent must have a route of transmission to the susceptible host, and the concentration of the agent must be high enough to cause disease. The biological hazards in the microbiology laboratory come from two major sources: (1) processing of the patient specimens and (2) handling of the actively growing cultures of microorganisms. Either activity puts the employee at risk of potential contact with infectious agents. The major routes of LAIs in the clinical laboratory are parenteral inoculations (e.g., needlesticks or contaminated sharps), spills and splashes onto skin or mucous membranes, ingestions (e.g., putting pens or fingers into the mouth), and inhalation of infectious aerosols. Families of microbiology personnel and persons who work in adjacent laboratories may also be at risk.

Many infectious agents pose a high risk to laboratory employees. *M. tuberculosis* has long been known to cause tuberculosis in laboratory workers exposed to aerosols created in processing sputum samples. A laboratory spill of active *M. tuberculosis*, which could easily aerosolize through the ventilation system, is of great concern. *Brucella* spp. and *Francisella tularensis* are other infectious agents that can be transmitted through inhalation of an aerosol created while processing or handling specimens (e.g., blood that may harbor these organisms) or cultures of the organism. *Coccidioides immitis*, an infectious fungus, can infect several people in a room if culture plates on which the organism is growing are opened in the absence of a BSC. In the 1970s, *Bacillus anthracis*

Fig. 4.3 **A**, Eye protection used when chemical splashing could occur. **B**, Integrated eye protection and mask. **C**, Laboratory coats. The material of the white laboratory coat slows the penetration of liquids that splash or soak it. The coat on the *right* is disposable.

caused the deaths of a laboratory worker's wife, who handled his contaminated laboratory coat, and their infant. Emerging pathogens, such as CoV-2, pose a major risk because there is often a lack of knowledge and experience among those working with these emerging infectious agents.

Bloodborne pathogens also pose a high risk. HBV can be transmitted to laboratory workers through needlestick injuries or cuts from other sharp instruments that have been contaminated with an infected patient's blood or body fluids or through contact with mucous membranes. Historically, health care workers have had a higher seropositivity rate for HBV than the general population. The CDC stated that before the institution of the hepatitis B vaccine in 1982, more than 10,000 health care workers were accidentally infected with this bloodborne pathogen annually. By 2001, the number had decreased to less than 400. HIV and hepatitis C virus are other bloodborne pathogens that may

be transmitted to laboratory personnel from contaminated specimens through a needlestick injury or another percutaneous route. All of these infectious agents must be handled with extreme care.

Because microbiology laboratory personnel frequently deal with various infectious agents—viral, fungal, bacterial, parasitic, and mycobacterial—LAIs are an obvious hazard and should be a concern for all laboratorians. Laboratorians must understand that they are at risk of an LAI because of the environment in which they work, and it should be the goal of laboratory management and laboratory workers to minimize this risk and follow all of the safety procedures employed by the laboratory for their protection. An example of the risk to laboratorians and their family members of LAIs was an outbreak of *Salmonella* Typhimurium infections. Between August 2010 and June 2011, 109 individuals were infected with this organism in over 38 states. An epidemiologic study identified

one possible link—exposure to microbiology laboratories, including teaching laboratories and clinical laboratories. The CDC, along with other organizations, identified areas where biosafety and laboratory safety improvements should be made. Some of the recommendations for students, laboratorians, laboratory directors and managers, and faculty included the following:

1. Laboratorians and students should know that bacteria handled in the laboratory can make people sick. These organisms can also make family members sick. Individuals must not take items into the laboratories that will be taken home, such as laboratory coats, pens, books, laboratory report forms, cell phones, and keys.
2. Students should have dedicated writing utensils and supplies at their workstations, and these should not leave the laboratory.
3. Laboratorians and students must be aware of the organisms with which they are working and what the signs and symptoms are if they become infected with one of these organisms.
4. Laboratorians and students must be educated and proficient in biosafety practices and techniques.
5. Laboratory coats should always be worn over personal clothing (appropriate PPE should be worn). Individuals should not leave the laboratory with PPE on; PPE always should be disposed of properly.
6. Handwashing sinks and supplies must be provided. Laboratorians and students should always wash their hands before leaving the laboratory.

Biological risk assessment is an important part of every microbiology laboratory safety program. Biological risk assessment is a process used to recognize the hazardous characteristics of infectious agents that may be encountered in the clinical microbiology laboratory. Also included in the risk assessment process are the laboratory practices that could result in an infectious exposure, the likelihood that an LAI will occur, and the consequences of that infection. Through this process, appropriate safety practices can be identified to protect laboratorians.

The hazardous risk characteristics of an agent are determined by the agent's ability to infect and cause disease in humans or animals; its virulence; the availability of treatment for the disease; and whether there are any preventive measures, such as a vaccine, that can be used to prevent disease by the agent. The World Health Organization (WHO) defined four **risk groups** for infectious agents based on the hazardous characteristics listed previously. The four risk groups, defined in the WHO classification of infectious microorganisms, correlate with the *biosafety levels* (BSLs) discussed later in this chapter, but are not always equal (Box 4.2). Other factors that must be considered when one is determining the correct BSL needed are the mode of transmission, the microbiological procedures that will be performed, and the experience of the staff members. A biological risk assessment is a comprehensive attempt to determine what controls should be used to protect the worker and environment from exposure. It is a subjective process, and different strategies can be used to perform the assessment. Five steps have been outlined in the CDC's "Guidelines for Safe

BOX 4.2 Classification of infective microorganisms by risk group

Risk group 1 (no or low individual and community risk)

A microorganism that is unlikely to cause human or animal disease.

Risk group 2 (moderate individual risk, low community risk)

A pathogen that can cause human or animal disease but is unlikely to be a serious hazard to laboratory workers, the community, livestock, or the environment. Laboratory exposures may cause serious infection, but effective treatment and preventive measures are available, and the risk of spread of infection is limited.

Risk group 3 (high individual risk, low community risk)

A pathogen that usually causes serious human or animal disease but does not ordinarily spread from one infected individual to another. Effective treatment and preventive measures are available.

Risk group 4 (high individual and community risk)

A pathogen that usually causes serious human or animal disease and that can be readily transmitted from one individual to another, directly or indirectly. Effective treatment and preventive measures are not usually available.

From World Health Organization. (2020). *Laboratory biosafety manual* (4th ed.). Geneva, Switzerland: World Health Organization.

Work Practices in Human and Animal Medical Diagnostic Laboratories" for performing a risk assessment. These are as follows:

1. Identify the hazards associated with an infectious agent or material.
2. Identify the activities that might cause exposures to the agent or material.
3. Consider the competencies and experience of laboratory personnel.
4. Evaluate and prioritize risks (evaluate the likelihood that an exposure would cause an LAI and the severity of consequences if such an infection occurs).
5. Develop, implement, and evaluate controls to minimize the risk for exposure.*

Processing of patient specimens

Labeling only specimens from patients with known hepatitis or acquired immunodeficiency syndrome (AIDS) and requiring "extra precautions" for dealing with these specimens does not provide adequate protection for laboratory workers. Many patients come to the emergency department or are admitted to the hospital with no diagnosis. These patients may be in the early stages of either disease or may be asymptomatic but still contagious. Because the incidence of hepatitis and AIDS is relatively high, the likelihood of exposure to one or both of these bloodborne pathogens is elevated. For

*Centers for Disease Control and Prevention. (2012). Guidelines for safe work practices in human and animal medical diagnostic laboratories *MMWR Suppl* 61(01), 1. Available at: https://www.cdc.gov/mmwr/preview/mmwrhtml/su6101a1.htm?s_cid=su6101a1_w.

this reason, standard precautions should be used when handling all patient samples.

When samples are received in the laboratory, often not enough information is available to assess the risk involved with processing the sample. Laboratory scientists do not know what infectious agents are present in the sample and will not know until the agent or agents have been identified. For this reason, it must be assumed that the specimen contains agents that correlate with at least a BSL-2, unless there is additional information suggesting that there may be an agent present from a higher-risk group. A common practice is to perform all specimen processing in a BSC because of the uncertainty regarding the infectious agents that might be present in the sample.

Case in point

A medical laboratory scientist is reading cultures at the bench. During her work, she isolates and identifies *Shigella sonnei*. She starts having watery diarrhea 48 hours later, which progresses to abdominal cramps and bloody stools. Because of her signs and symptoms, her primary care practitioner orders a stool culture.

Issues to consider

After reading the patient's case history, consider:

- The identity of the organism causing the infection
- The potential for an LAI
- The importance of laboratory safety procedures

Working with actively growing cultures

Many of the guidelines in place for the protection of microbiology personnel against exposure to bloodborne pathogens also apply to working with cultures of microorganisms at the bench. Some of the safety precautions that should be used in the microbiology laboratory are the following:

1. Hands must be **washed** frequently and kept away from the nose, mouth, and eyes. Hands should be washed after removal of gloves.
2. Appropriate PPE should be worn.
3. Adhesive bandages or small finger cots should be worn directly over cuts or hangnails.
4. Plates should not be waved in front of the face to determine the odor of the organism.
5. Splash guards are recommended for any procedure that may produce splashes, such as work at the blood culture bench. Gram-negative coccobacilli from a blood culture should be handled in a BSC.
6. Do not use open flames in the laboratory.
7. Any plates growing a fungus should immediately be sealed, and the culture should be worked on in a BSC.
8. Any cultures suspected of growing other potentially aerosolized infectious agents, such as *M. tuberculosis* or *Brucella* spp., should be worked on only in a BSC.

In an effort to educate individuals at risk of LAI, the CDC publishes a manual entitled *Biosafety in Microbiological and Biomedical Laboratories* every few years, which contains important information on the degree of risk of biological agents for laboratory workers and the safety procedures that should be used when working with infectious agents.

Case check 4.3

S. sonnei was isolated from the stool culture of the laboratory scientist from the Case in Point. The laboratory supervisor investigated the incident. It was discovered that the laboratory scientist had her cell phone with her in the laboratory and used the phone while working at the laboratory bench. She stated that at the end of her shift she wiped the phone with alcohol. It appeared that the LAI occurred because the laboratory scientist did not follow the safety protocols in the microbiology laboratory.

Biological safety cabinets

BSCs are a form of engineering control that is used throughout the microbiology laboratory. These hoods are a type of containment barrier that protects the worker from the aerosolized transmission of infectious agents. Any procedure that has the ability to create aerosols should be performed in a BSC. Microbiology clinical samples should also be handled within a BSC. There are three types of BSC: class I, class II, and class III (Fig. 4.4).

A BSC must be maintained, inspected, and used properly, and it is imperative that the laboratory worker understand the functions and limitations of the unit. The most common type of BSC used in a microbiology laboratory is the class II. Box 4.3 provides a few guidelines to follow to ensure the proper use of a BSC.

Biosafety levels

LAI may occur through error, accident, or carelessness. However, the mode of transmission is unknown in many LAIs. For this reason, strict guidelines have been instituted to protect the worker during all laboratory tasks. Earlier in this chapter, the classification of infectious microorganisms into risk groups was discussed. When considering which BSL to use, the laboratorian should know the risk group for the agents being handled, the mode of transmission for the agents, and the procedures that will be performed (e.g., whether aerosols will be created). The *Biosafety in Microbiological and Biomedical Laboratories* manual from the CDC recommends that the BSLs should be used when working with particular agents and performing certain procedures. Four BSLs with guidelines were established for each level for protection.

Biosafety level 1

Infectious agents that would be classified as requiring BSL-1 containment are agents that are well classified and are not known to consistently cause disease in healthy adults. These agents pose a minimal threat to laboratory personnel and

Fig. 4.4 **A**, The class I biological safety cabinet (hood) uses an exhaust fan to move air inward through the open front. The air is circulated within the safety hood, passing through a high-efficiency particulate air (HEPA) filter before reaching the environment outside the hood. **B**, The class II biological safety cabinet is the most common in microbiology laboratories. Air is pulled inward and downward by a blower and passed up through the air flow plenum, where it passes through a HEPA filter before reaching the work surface. A percentage of the remaining air is HEPA filtered before reaching the environment. **C**, The class III biological safety cabinet is a self-contained ventilated system for highly infectious microorganisms or materials and provides the highest level of personal protection. The closed front contains attached gloves for manipulation on the work surface. *Note:* Chemical fume hoods cannot be used as biological safety cabinets, and biological safety cabinets cannot be used as chemical fume hoods.

BOX 4.3 Proper use of a biological safety cabinet (BSC)

- Be aware of the functioning and limitations of the unit. You and your specimen are being protected solely by an air curtain barrier, and anything that disrupts this curtain threatens your safety. Ensure that the cabinet has been inspected within the past year and that the air pressure readings across the HEPA filter are within specifications.
- Plan your work, anticipating the order of events.
- Turn on the incandescent lights and the blower fan. Be sure the UV light is off. Wait 15 to 30 minutes to ensure satisfactory establishment of the air curtain.
- Wash your hands, and then gown and glove. Wear a mask or other personal protective equipment as appropriate.
- Decontaminate the interior work surfaces by cleaning them thoroughly with 70% ethanol.
- Organize all necessary work materials, and place them in the cabinet. Do not place any extra items in the cabinet. Ensure that both the front intake grill and the rear-wall or floor exhaust grills are unobstructed.
- Segregate clean and contaminated items, and place them to minimize subsequent movement with the BSC. The discard bucket/pan should be near the rear of the cabinet but not obstructing the exhaust grill.
- Do not use open flames in the unit. Instead, use disposable supplies or an incinerator.
- All arm movements into and within the cabinet should be slow and deliberate so as to minimize disruption of the air curtain. Allow adequate time at the conclusion of movement for the air curtain to reestablish itself.
- When work is completed, remove all nonpermanent items from the BSC, and allow the cabinet fans to continue running for at least 30 minutes to ensure thorough filtering of the inside air (assuming the fans are not left on permanently). Turn on the UV lights to disinfect the interior of the cabinet.

BSC, Biological safety cabinet; HEPA, high-efficiency particulate air; UV, ultraviolet.

Data from Kruse, R. H., Puckett, W. H., & Richardson J. H. (1991). Biological safety cabinetry. *Clinical Microbiology Reviews*, 4(2), 207–241.

the environment. Safety guidelines for handling these agents include the following:

1. Access to the laboratory is limited or restricted, and there must be a biohazard sign posted at the entrance of the laboratory.
2. Employees must wash their hands after they have removed their gloves, after they have handled live organisms, and before they leave the laboratory.
3. Employees must follow basic work practice controls.
4. Employees must follow OSHA guidelines for handling needles and sharps.
5. Work surfaces must be decontaminated after completion of work and any time there has been a spill of potentially infectious material.
6. Laboratory coats and gloves should be worn and other PPE, such as face shields and eye protection, may be needed when there is a potential for splashes or sprays of infectious or other hazardous materials.
7. Cultures and stock material must be decontaminated before disposal.
8. An insect and rodent control plan must be in effect.
9. The laboratory facility should be designed so it can be easily cleaned. Carpets and rugs should not be used. The laboratory must be equipped with handwashing sinks, an eyewash station, and adequate illumination.

Laboratory work can be conducted on open bench tops in a BSL-1 laboratory. Employees should be educated in laboratory procedures and supervised by a scientist with training in microbiology or a related science. Standard microbiology practices should be followed at all times. Examples of BSL-1 organisms include *Bacillus subtilis* and *Klebsiella aerogenes*.

Biosafety level 2

Infectious agents that require BSL-2 containment and practices are agents that pose a moderate potential hazard for the employees and the environment. The guidelines are the same as for BSL-1 with added precautions for BSL-2 agents as follows:

1. Employees in the laboratory must have specific education in the handling of pathogenic agents and should receive annual updates or additional training as needed.
2. Access to the laboratory is limited when work is being conducted. The laboratory director is ultimately responsible for determining who may enter or work in the laboratory.
3. Laboratorians should receive immunizations or tests for agents handled or for agents that could potentially be in the laboratory environment (e.g., hepatitis B vaccination and the tuberculin skin test).
4. A biosafety manual must be developed and updated.
5. A BSC must be used whenever there is a potential for creating infectious aerosols or splashes or when high concentrations of infectious agents are used. The recommended BSC is class II.
6. All PPE must be worn. Gloves must be worn to protect hands from exposure to hazardous materials.
7. Extreme precautions are taken with contaminated sharp items. The use of needles and syringes is restricted within the laboratory to only times when there is no alternative equipment that can be used.

Examples of BSL-2 organisms include HBV, HIV, *Salmonella* spp., and *Toxoplasma gondii*.

Biosafety level 3

BSL-3 containment and practices are required for infectious agents that are either indigenous or exotic. These agents have the potential for aerosol transmission, and diseases with these agents can have serious lethal consequences. The guidelines for BSL-2 laboratories must be followed along with the more stringent guidelines needed to handle BSL-3 agents safely. Laboratory personnel must have specific training in handling of these pathogenic and potentially lethal organisms. A few of the special BSL-3 guidelines are as follows:

1. The handling of infectious materials, samples, and cultures must occur within a BSC or other physical containment device.
2. Personnel must wear appropriate PPE. Gloves must be worn to protect hands from exposure to hazardous materials.
3. The BSL-3 laboratory should be separated from the other parts of the building and should be accessed through two self-closing doors. An anteroom may be used for access.
4. The BSL-3 laboratory requires a ducted air ventilation system that must provide sustained directional air flow. This directional air flow pulls air from “clean” areas toward “potentially contaminated” areas (negative air pressure).
5. The ceilings and floors must be solid, and any seams must be sealed.
6. All parts of the laboratory must be constructed for easy cleaning and decontamination.

Examples of BSL-3 agents include *M. tuberculosis*, St. Louis encephalitis virus, *Coxiella burnetii*, and CoV-2 (the cause of COVID-19).

Biosafety level 4

BSL-4 containment and practices are required when working with agents that are dangerous and exotic. These agents have a high risk of causing life-threatening infections, can be transmitted by aerosols, or have an unknown risk of transmission. Vaccines are typically not available. As in all microbiology practices, specific training is required. Laboratory personnel must receive thorough training in the handling of these dangerous agents, and they must be trained in how to use the containment barriers that are in place for protection. The BSL-4 facility either is located in a separate building or is in an isolated zone within a building. This facility is isolated from all other areas, and access is strictly controlled. The guidelines listed for BSL-3 must be followed along with additional guidelines for handling BSL-4 agents. There are two types of BSL-4 laboratories: cabinet and suit. In the cabinet laboratory, all work is performed within a class III BSC. In a suit laboratory, personnel wear a positive pressure protective suit to perform all work. Some of the additional guidelines are as follows:

1. Access is strictly controlled, and the supervisor has the ultimate responsibility for who has access. A logbook is maintained to document all personnel who enter and exit the laboratory.

2. As required by all levels, a biohazard sign must be posted outside the door with the potential hazards; the laboratory director's name; and any special requirements, such as immunizations, for entering the area.
3. All personnel must demonstrate high proficiency in standard and special microbiology practices.
4. Policies and procedures are established on the collection and storage of serum samples from at-risk personnel.
5. Personnel enter and exit the laboratory through the clothing change room. When personnel leave the laboratory, they must completely change clothes and shower. The clothes are then decontaminated before being laundered.
6. The BSL-4 laboratory has a dedicated nonrecirculating ventilation system, which is filtered through a HEPA filter before being exhausted.
7. All material is decontaminated before leaving the BSL-4 laboratory.

Examples of BSL-4 agents include Marburg and Congo-Crimean hemorrhagic fever viruses.

Hazardous waste

The clinical laboratory is responsible for the proper handling and disposal of all of the waste it generates. The scope of hazardous waste comprises more than just infectious waste. The *Clinical Laboratory Waste Management Approved Guideline*, 3rd edition, by the Clinical Laboratory and Standards Institute, provides information for laboratory managers on the regulations governing hazardous wastes and addresses the following types of waste: chemical, infectious, radioactive, sharps, multihazardous, and nonhazardous. The guideline also emphasizes methods to reduce waste generation and methods to reduce the volume of and toxicity of unavoidable wastes.

Disposal of infectious waste

In addition to laboratory employees who work with potentially infectious material, the general public must be protected from exposure to these same materials after the laboratory or hospital has disposed of them. The surfacing of contaminated needles and other sharps along lake and ocean beaches led to a public outcry to make hospitals accountable for their infectious waste disposal. In an effort to handle this problem, the U.S. Congress passed the Medical Wastes Tracking Act in 1988 to regulate the states of New York, New Jersey, Connecticut, and Rhode Island as well as Puerto Rico. These regulations went into effect on June 24, 1989, and expired on June 21, 1999. This act allowed the EPA to gather information and focus attention on the problem of medical waste and provided a basis for other states and federal agencies to develop policies on the disposal of medical waste.

The microbiology laboratory's safety program must follow state and local regulations for the safe disposal of its infectious waste, usually by either autoclaving or incineration. Warning signs containing the warning symbol for biohazardous materials must be placed on all biohazard waste and material disposal containers. Figs. 4.5 and 4.6 show disposal containers appropriate for contaminated and biohazardous materials.

Fig. 4.5 Biohazard bag used to dispose of culture plates and other nonsharp contaminated materials. The bag is sealed and incinerated. The biohazard symbol is in the center of the bag.

Hazardous waste reduction

The EPA has also made recommendations for hazardous waste reduction through the following methods:

1. Substitute less hazardous chemicals when possible.
2. Develop procedures that use less of a hazardous chemical.
3. Recycle chemicals when possible.
4. Segregate infectious wastes from uncontaminated trash.
5. Substitute micromethodology in antimicrobial susceptibility testing and identification of organisms to reduce the volume of chemical reagents as well as infectious waste.

Chemical safety

Chemicals used in the clinical laboratory can be hazardous to the laboratory scientist. The toxic risks of a chemical are related to the extent of exposure and to the inherent toxicity of the chemical. The possible routes of exposure for chemicals are through the skin, eyes, mucosa, gastrointestinal tract, and respiratory tract. The OSHA addresses employee safety with hazardous chemicals in 29 Code of Federal register (CFR) 1910.1200, Hazard Communication Standard (HCS). The HCS focuses on the proper classification of chemicals by manufacturers and importers as well as the safety practices

Fig. 4.6 A and B, Examples of biohazard containers for disposable needles, glass slides, and other sharp materials.

for employers and employees. It requires a laboratory chemical hygiene plan and a hazard communication program, and it states that all clinical laboratory personnel should have a thorough working knowledge of the hazards of the chemicals with which they come into contact, or **employee right-to-know**, and must receive chemical safety training annually. The National Research Council publication *Prudent Practices in the Laboratory: Handling and Disposal of Chemicals* can be used by laboratory managers when developing a chemical hygiene plan for a laboratory. All chemicals in the workplace must be identified and clearly labeled with the **National Fire Protection Association (NFPA) 704 hazard-rating diamond**, stating risk for flammability, reactivity, and health (Fig. 4.7).

Safety data sheets

Safety data sheets (SDSs) are provided by the manufacturer or distributor of hazardous chemicals. Although there is no accepted format regarding what is contained in an SDS, some of the information that should be provided is as follows:

- Name, address, and telephone number of the manufacturer
- Chemical and synonym names and a list of the hazardous ingredients
- Chemical characteristics, such as vapor pressure and flash point, and the physical characteristics (potential for fire, explosion, and reactivity)
- Health hazards of the hazardous chemical (signs and symptoms of exposure and any medical conditions that can be caused by exposure)
- The primary routes of entry and the target organs
- Precautions for safe handling and use, including appropriate hygienic practices

HAZARDOUS MATERIALS CLASSIFICATION CLASIFICACION DE MATERIALES PELIGROSOS

- Any generally applicable control measures, such as appropriate engineering controls, work practices, or PPE
- Emergency and first aid procedures
- Spill cleanup procedure
- Disposal recommendations

An example of an SDS is shown in Fig. 4.8. These documents should be kept on file and made available to every employee. Other examples of common hazardous chemicals found in the microbiology laboratory are listed in Box 4.4.

No decomposition if used according to specifications.
- **Possibility of hazardous reactions** No dangerous reactions known
- **Conditions to avoid** No further relevant information available.
- **Incompatible materials:** No further relevant information available.
- **Hazardous decomposition products:** No dangerous decomposition products known.

11 Toxicological information

- **Information on toxicological effects**
- **Acute toxicity:**
- **Primary irritant effect:**
- **on the skin:** No irritating effect.
- **on the eye:** No irritating effect.
- **Sensitization:** No sensitizing effects known.
- **Additional toxicological information:**
The product is not subject to OSHA classification according to internally approved calculation methods for preparations.
When used and handled according to specifications, the product does not have any harmful effects according to our experience and the information provided to us.
This product or product container contains natural rubber latex which may cause allergic reactions. People with known or suspected allergies to latex should use appropriate safety precautions when handling.
- **Carcinogenic categories**
- **IARC (International Agency for Research on Cancer)**
None of the ingredients is listed.

12 Ecological information

- **Toxicity**
- **Aquatic toxicity:** No further relevant information available.
- **Persistence and degradability** No further relevant information available.
- **Behavior in environmental systems:**
- **Bioaccumulative potential** No further relevant information available.
- **Mobility in soil** No further relevant information available.
- **Ecotoxicological effects:**
- **Other information:**
The ecological effects have not been thoroughly investigated, but currently none have been identified.
- **Additional ecological information:**
- **General notes:** Generally not hazardous for water.
- **Results of PBT and vPvB assessment**
- **PBT:** Not applicable.
- **vPvB:** Not applicable.
- **Other adverse effects** No further relevant information available.

13 Disposal considerations

- **Waste treatment methods**
- **Recommendation**
Dispose of material in accordance with federal (40 CFR 261.3), state and local requirements.
This product is not considered a RCRA hazardous waste.
Smaller quantities can be disposed of with solid waste.
- **Uncleaned packagings:**
- **Recommendation:** Disposal must be made according to state and federal regulations.
- **Recommended cleansing agent:** Water, if necessary with cleansing agents.

FIG. 4.8, cont'd

BOX 4.4 Hazardous chemicals commonly used in the microbiology laboratory

Flammables

- Methanol
- Acetone
- Ethanol

Potential or proven carcinogens

- Aniline (crystal violet) stain
- Auramine-rhodamine stain

Irritants and corrosives

- Hydrogen peroxide
- Acids: HCl, H₂SO₄, acetic acid
- NaOH

Chemical storage

Chemicals should never be stored alphabetically. Chemicals must be stored according to established rules of compatibility to prevent contact between reactive substances. Do not store alkali metals (e.g., sodium, potassium) with carbon dioxide, chlorinated hydrocarbons, or water. Acids and bases should never be stored together. Also, acids such as acetic acid and sulfuric acid should never be stored with oxidizing agents. Halogens are incompatible with ammonia, acetylene, and hydrocarbons. Flammable chemicals should be stored in a flammable storage cabinet. Within the laboratory, chemicals should be stored in amounts reflective of the daily requirements. Bulk stocks should be stored in specially designated areas and not in the laboratory. It is good practice to store corrosives in trays as secondary containment because of the potential for shelves to become damaged.

Chemicals inventory

The laboratory must maintain a current inventory of chemicals, which must be updated annually, along with the SDSs for those particular chemicals. The following four sources should be consulted in preparing an inventory:

1. 29 CFR Part 1910, Subpart Z, Toxic and Hazardous Substances, OSHA
2. National Toxicology Program Annual Report on Carcinogens
3. International Agency for Cancer Research Monographs
4. Manufacturers' SDSs

Hazardous chemical classification

Chemical manufacturers and importers classify chemicals as required by OSHA Standard 1910.1200(d). Chemical manufacturers and importers determine the hazard classes and the category of each chemical by considering the comprehensive range of scientific literature related to a chemical. There is no requirement for manufacturers or importers to perform tests to determine a chemical classification. Chemical manufacturers and importers determine whether a chemical is carcinogenic by referring to the National Toxicology Program and the International Agency

for Research on Cancer annual reports. End-users of chemicals are not required to classify chemicals; however, they may conduct their own classification studies if they deem such procedures appropriate for their facility.

Laboratory safety for hazardous chemicals

Laboratory fume hoods are one of the most important pieces of equipment for protecting workers from exposure to hazardous chemicals. Fume hoods must be provided to prevent inhalation of fumes and should be evaluated at least annually for adequate face velocity (average velocity of the air drawn through the face of the hood) and proper operation. Fume hoods should be vented. PPE, including appropriate gloves, laboratory coats, and eyewear, must be used in the case of a small spill to protect workers from exposure. A dust mask or respirator may be appropriate depending on the material spilled.

Chemical spills

Spillage in the laboratory is unavoidable and unpredictable. Many chemical manufacturers develop charts describing the procedure for managing spills. Acid and base spill kits and flammable spill kits should be kept in areas where such substances are used. Equipment such as protective clothing, scoops and dust pans, forceps for picking up glass, and buckets should be kept in a designated area. In the event of a large spill, the Environmental Health and Safety Department should be called for assistance.

Signage

Signage is important safety equipment. Warning signs and symbols, as shown in Fig. 4.9, must be placed in appropriate locations. Employees must be able to recognize each of these symbols and must be knowledgeable about the danger each indicates and the proper precautions that must be observed.

Fire safety

Bunsen burners and other open-flame burners in most cases have been replaced with other methods or techniques, such as fixing slides with methanol or slide warmers and using disposable loops. Bunsen burners and open-flame burners are among the biggest sources of fire hazards in the clinical microbiology laboratory. Employees must strive not to be careless or negligent in the use of this equipment. Flammable materials should never be opened near a Bunsen burner in use. Open flames should not be left unattended, and the laboratorian should always be sure to turn off the gas when finished. As previously noted, it is important to never place an open flame inside a BSC.

Another hazard associated with Bunsen burners and other open-flame burners is the fuel. Bunsen burners use gas. A leaking gas line may be a source of explosion or may cause illness in employees who work near the leak. The gas hose should be inspected on a regular basis for cracks, holes, pinched points, or other defects, and the hose should be replaced if any defects are found. If a leak is suspected or the appliance is newly connected, leaks can be checked for by lightly spraying the tubing with soapy water. If bubbles appear when the gas

Radioactive material present

Fig. 4.9 Miscellaneous warning signs and symbols.

is on, there is a leak at that point. Other burners use a flammable liquid as the fuel, which is in itself a hazard. Other sources of ignition include heating elements, hot plates, incinerators, and spark gaps in motors and light switches.

The OSHA requires employers to have an emergency action plan, which includes what to do in the event of a fire. The emergency action plan must be written, and it must be kept in the workplace and available to all employees. All personnel must be thoroughly trained in the procedure for responding to a fire emergency. Most institutions use the acronym RACE:

- **Rescue:** Remove anyone who is in danger. The safety of handicapped personnel (e.g., deaf, or physically disabled) should be a priority.
- **Alarm:** Know where the nearest fire pull box or alarm station is located and the number to call to report the fire.
- **Contain:** Close doors to contain fire and smoke.
- **Extinguish:** Use the properly rated fire extinguisher on small fires (Table 4.5).

Table 4.5 Classes of fire extinguishers

Symbol	Class	Use
	A	Fires in ordinary combustible materials, such as wood, cloth, paper, rubber, and many plastics; contains water or dry chemical to cool
	B	Fires in flammable liquids, gases, and greases; contains CO ₂ or dry chemical to smother
	C	Fires involving electrical equipment, for which the electrical nonconductivity of the extinguishing media is important; contains CO ₂ or dry chemical to smother without damaging the equipment

If the situation is out of control, the best course of action is to evacuate. The fire evacuation plan must be posted, and employees should be familiar with fire exit locations and evacuation procedures. Periodic fire drills should be conducted to ensure that all personnel react quickly and efficiently in case of a real fire emergency. The drills should include both exit and nonexit procedures. Exit drills familiarize personnel with escape routes and location of fire doors and stairwells. Nonexit procedures alert personnel to the potential for evacuation if the fire is located elsewhere in the building. The laboratory should be kept free from clutter (e.g., do not leave boxes, cords, reagents on the floor), and exits should always remain clear of obstructions.

Thermal injuries

Personnel should be warned of any hot surface or situation in which the potential for burns is present. Use of long thermal gloves that extend to the shoulder is recommended when reaching into autoclaves or hot-air ovens. Signs should be posted warning employees about hot instruments or flasks that have just been sterilized. Burns may also come from extremely low temperatures found with use of liquid nitrogen or freezers that maintain temperatures less than -70°C .

Storage of compressed gases

Flammable and nonflammable gas cylinders in use in the laboratory must always be properly restrained and stored in bulk, and they must be secured in vented areas. In the laboratory, cylinders must be located well away from open flames and other heat sources. Because a leaking pressurized gas cylinder is a potential “missile,” care must be taken to avoid accidental breakage or removal of the pressure valve on top. The metal cap that protects this valve on top of the cylinder must be kept in place during transportation and when the cylinder is not in use.

Electrical safety

Today’s microbiology laboratories contain many instruments. All laboratory electrical equipment must conform to national electrical safety standards and codes. Each instrument must undergo regular preventive maintenance to ensure that it is functioning properly and in the best repair.

Electrical cords should be checked for fraying. All cords should have grounded (three-pronged) plugs. The College of American Pathologists, an organization that provides accreditation to laboratories, requires electrical grounding and leakage checks on instruments before they are put in use, after repairs or modifications, and when there is a suspected problem. Electrical equipment should never be placed near safety showers because of the risk of electrocution.

Miscellaneous safety considerations

Back safety

The best way to care for the back is to prevent back injuries. Carrying heavy trays of culture plates, lifting heavy loads into and out of autoclaves, and sitting or standing improperly all can contribute to back stress or injury. The following are some ways to prevent back injuries:

- Use the legs to lift, not the back.
- Keep loads close to the body when transporting them.
- Ask for assistance or use a cart when a load is too heavy.
- Use good posture.
- Stay physically fit.

First aid training

All personnel should be trained in cardiopulmonary resuscitation and other lifesaving first aid so they will be able to act quickly in an emergency involving either fellow workers or patients.

Immunizations

The OSHA requires that the HBV vaccine be offered free of charge to all personnel who are at risk of exposure to bloodborne pathogens. Microbiology personnel working with sputum specimens or mycobacterial cultures should be screened for exposure to *M. tuberculosis* with an annual tuberculin skin test.

Safety training

All clinical laboratories must offer their employees safety training, and this training must be documented. The training must include the following safety issues:

- *Fire*: Knowledge of how and when to report fires, the location of the nearest alarm box and fire extinguishers, how to use fire extinguishers in small fires, and blocking of fire doors
- *Hazardous materials management*: How to use SDSs
- *Proper storage of gases*
- *Bloodborne pathogens program*: Appropriate practice of infection control, how to handle sharps, compliance with exposure control plan, and handling of biological spills

Safety training programs for microbiology personnel should be conducted annually to keep safe techniques fresh in everyone’s mind. New personnel should be thoroughly trained in safety procedures. It is a good idea to focus on one safety topic at a time and to make the training sessions enjoyable. Safety is each employee’s responsibility.

Bioterrorism and the clinical microbiology laboratory

Clinical microbiology laboratorians are critical players in the early detection of a bioterrorism event. In the September 2001 anthrax incident, laboratorians performed the testing that identified the infectious agent. The CDC has developed a program that identifies how health care workers and other public health officials should respond to bioterrorism event. This program (Emergency Preparedness and Response Program) addresses biological agents and diseases, laboratory information, training, preparedness and planning, and surveillance. Refer to [Chapter 30](#) for more information on agents of bioterrorism.

Laboratory response network

The CDC developed the **Laboratory Response Network** (LRN) in 1999. This program established a network of laboratories that could respond quickly and effectively to biological and chemical terrorism. The LRN developed three levels of laboratories: (1) sentinel laboratories, (2) reference laboratories, and (3) national laboratories. The roles and responsibilities of each of these levels are defined to provide rapid and safe identification of biological agents during a bioterrorism event. The LRN is discussed in [Chapter 30](#).

Sentinel laboratories constitute most hospital-based microbiology laboratories and are divided into two levels. Advanced sentinel clinical laboratories function at the frontlines and have the most capability. The role of these sentinel laboratories is to recognize possible bioterrorism agents and to perform basic testing to rule out these agents or to refer suspicious specimens or isolates to the LRN reference laboratory. Basic sentinel clinical laboratories have fewer analytical capabilities but may handle suspect samples and would refer these specimens to an LRN reference laboratory. The role of reference laboratories and national laboratories in the LRN is to perform confirmatory testing. At the present time, more than 100 laboratories are members of the reference laboratory category. The national laboratories in the LRN are the CDC, the U.S. Army Medical Research Institute of Infectious Diseases, and the Naval Medical Research Center.

Safety during a possible bioterrorism event

The biggest threat with handling agents likely involved in a bioterrorist event is not recognizing the risk associated with these infectious agents and not following the safety procedures instituted in the laboratory for protection. Specimen processing of samples from a possible bioterrorism event should occur within a class II BSC. However, it is likely that the first patients seen in an event will not be identified as victims of bioterrorism. Therefore the cultures from these patients could cause the greatest risk to laboratorians.

The agents that pose the greatest risk are agents transmitted by aerosols, and all laboratorians must remember that

many of the procedures that are performed in the laboratory create aerosols, such as pipetting, flaming loops, streaking plates, and centrifugation. When a bioterrorism agent is suspected, all manipulations of the culture should be performed using BSL-3 guidelines. Sentinel laboratories should *not* accept environmental samples for testing because of the unknown nature of the sample.

Packaging and shipping of infectious substances

Laboratory personnel who are involved in the packaging and shipping of infectious materials must be trained and certified before shipping infectious material. Personnel must be retrained on a regular basis. The International Air Transport Association, the International Civil Aviation Organization, and the U.S. Department of Transportation regulations must be followed when packaging and shipping infectious agents. Laboratory personnel must be aware of what agencies will transport these materials to the identified LRN reference or national laboratory.

POINTS TO REMEMBER

- Physical and chemical methods may be used in the process of sterilization to remove all forms of life.
- Disinfection involves removal of pathogenic organisms but may not include removal of bacterial or other spores; most disinfectants are chemical agents.
- Factors that influence the degree of killing include types of organisms and number of organisms present, concentration of disinfecting agent, amount of soil present, and nature of the surface to be disinfected.
- Antiseptics are designed to reduce the bacterial load of living tissues.
- Disinfectants are designed to be used on inanimate objects to kill or destroy disease-producing microorganisms.
- There are two options a manufacturer can pursue in seeking approval for a disinfectant product: submission of an NDA or OTC drug review known as the *monograph system*.
- Antimicrobial agents for health care personnel use must meet certain standards that demonstrate the product's safety and efficacy.
- Major sources of biological hazards come from patient samples during processing and handling of actively growing culture materials.
- Protective equipment should be used appropriately.
- Safety policies and procedures should be reviewed annually and always followed.
- The microbiology safety program includes proper and safe disposal of infectious waste material.
- OSHA regulations for bloodborne pathogen protection should be followed.
- Chemical and fire safety hazards must be identified, and measures to prevent chemical spills should be employed.
- Continuing education programs to train laboratory personnel in all aspects of laboratory safety and exposure control should be in place.

LEARNING ASSESSMENT QUESTIONS

1. What is the difference between sterilization and disinfection?
2. Explain situations in which you would use a disinfectant and an antiseptic.
3. Describe the difference between physical and chemical methods of disinfection and sterilization.
4. What method is required to kill endospores effectively?
5. List and describe factors that influence the degree of killing during disinfection and sterilization.
6. Explain EPA regulations on chemical surface disinfectants and FDA regulations on chemical skin antiseptics.
7. Transient biota of the skin is defined as:
 - a. Organisms that are contracted from the environment
 - b. Organisms that are contracted from other persons
 - c. Organisms that are not part of the established normal biota
 - d. All of the above
8. Which of the following characteristics should be considered when selecting an antimicrobial agent?
 - a. Spectrum of activity
 - b. Rate of action
 - c. Mechanism of action
 - d. All of the above
9. List the mechanism of action for each type of chemical agent commonly used in antiseptics and disinfectants.
10. Explain the use of health care personnel handwash, surgical hand scrub, and patient preoperative skin preparation.
11. How does the Coronavirus Aid, Relief, and Economic Security Act (CARES Act) reform the OTC drug review?
 - a. Includes important reforms that modernize the way OTC monographs are regulated in the United States
 - b. Replaces the rulemaking process with an administrative order process for issuing, revising, and amending OTC monographs
 - c. Provides the FDA the authority to assess and collect user fees dedicated to OTC monograph drug activities
 - d. All of the above
12. The OSHA requires employers to offer the hepatitis B virus vaccine free of charge to employees who are at risk for exposure to hepatitis B virus. True or False?
13. Safety data sheets contain information relating to which of the following?
 - a. Bloodborne pathogens
 - b. Fume hoods
 - c. Chemical safety
 - d. Fire extinguishers
14. Which of the following would be a correct definition of standard precautions?
 - a. Wearing only gloves to handle blood and body fluids
 - b. Viewing all specimens as potentially infectious and using the appropriate protective equipment
 - c. Delaying testing of blood and body fluids pending results of HIV and hepatitis B antigen testing
 - d. Flagging only specimens that come from patients who are known HIV carriers for "extra precautions"
15. Which type of filter does a class II BSC use to remove infectious agents?
 - a. Millipore filter
 - b. HEPA filter
 - c. Dust filter
 - d. Charcoal filter
16. Infectious agents can enter the body through which of the following routes?
 - a. Inhalation
 - b. Ingestion
 - c. Inoculation
 - d. All of the above
17. Employees can remember the steps to take in case of a fire by remembering which of the following acronyms?
 - a. RUSH
 - b. REST
 - c. RACE
 - d. RISK
18. How often must safety training for laboratory employees be conducted for compliance with OSHA regulations?
 - a. Annually
 - b. Quarterly
 - c. At the time of employment only
 - d. No set requirement
19. Briefly describe the NFPA hazard-rating diamond found on all chemical containers to warn employees of potential hazards associated with that chemical.
20. Washing hands frequently, disinfecting work areas, using needle-resheathing devices, performing procedures in a manner to reduce splashes, and transporting specimens in well-constructed leakproof containers are examples of which of the following?
 - a. Standard precautions
 - b. Work practice controls
 - c. Responsible methods of fire safety
 - d. Chemical hygiene
21. The OSHA Bloodborne Pathogens Standard outlines the safety requirements that an employer must have in place to protect the employee from bloodborne pathogens. This is called:
 - a. Laboratory Response Network
 - b. Work practice controls
 - c. Exposure control plan
 - d. Emergency action plan
22. A patient with active tuberculosis is admitted to the hospital. What type of precautions above and beyond standard precautions will be followed for this patient?
 - a. Airborne precautions
 - b. Contact precautions
 - c. Droplet precautions
 - d. No necessary precautions
23. The following BSL practice is required for agents that may cause serious disease:
 - a. BSL-1
 - b. BSL-2
 - c. BSL-3
 - d. BSL-4
24. The risk group classification for infectious agents that can cause human disease but for which effective treatments and preventive measures are available is:
 - a. Risk group 1
 - b. Risk group 2
 - c. Risk group 3
 - d. Risk group 4
25. OSHA Bloodborne Pathogens Standard requires employers to have an exposure control plan and should include:
 - a. A plan to investigate all exposure incidents and a plan to prevent these from recurring

- b. Method of compliance for standard precautions
- c. Personal protective equipment (PPE)
- d. Guidelines for the handling and disposal of regulated waste
- e. All of the above

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Differentiate quality control (QC) from quality assurance as it applies in the clinical microbiology laboratory.
2. Describe the three phases in a laboratory workflow and what typically occurs in each phase.
3. Discuss the purpose of an organization's mission and vision statements and shared values.
4. Differentiate personnel competency assessment from proficiency testing.
5. Describe the various performance indicators applied in performance improvement.
6. Explain the components of a performance monitor.
7. Justify the benefit of implementing Lean and Six Sigma in the microbiology laboratory.
8. Apply performance monitors such as Problem-Action Form and Learn from Defect.
9. Define benchmarking as it applies to the microbiology laboratory.
10. Establish QC guidelines in a microbiology laboratory including how to monitor equipment maintenance and performance, culture media and reagent performance, personnel competency, use of stock cultures, and the development and updating of procedure manuals.
11. Properly document and institute correction actions.
12. Define individualized QC plan.
13. Explain the significance of customer concept in quality management.
14. Differentiate analytic sensitivity from analytic specificity of laboratory tests.
15. Justify the value of clinical sensitivity and specificity of laboratory tests.
16. Differentiate prevalence from incidence of a disease.

17. Discuss the importance of prevalence in determining the predictive values of laboratory tests.
18. Demonstrate how predictive values of laboratory tests are calculated.
19. Apply the concepts of predictive values of laboratory tests to various clinical examples.
20. Using the formula, calculate the sensitivity and specificity of a particular diagnostic laboratory test.

KEY TERMS

Accuracy	Individualized quality control plan (IQCP)
Analytic activity	Lean
Analytic sensitivity	Learn from Defect
Analytic specificity	Negative predictive value (NPV)
Bayes's theorem	Outcome monitors
Benchmarking	Performance improvement (PI)
Bias	Postanalytic activity
Clinical (diagnostic) sensitivity	Positive predictive value (PPV)
Clinical (diagnostic) specificity	Prenalytic activity
Clinical Laboratory Improvement Amendments (CLIA)	Precision
Clinical and Laboratory Standards Institute (CLSI)	Predictive value
College of American Pathologists (CAP)	Prevalence
Competency	Preventive maintenance
Continuous quality improvement (CQI)	Process monitors
Continuing education (CE)	Proficiency testing
Cross-functional teams	Q-probes
Customer concept	Quality assurance (QA)
Detection limit	Quality control (QC)
Focused monitors	Six Sigma
Incidence	Test validation
	The Joint Commission (TJC)
	Total quality management (TQM)

Case in point

A 5-year-old girl complains of a sore throat. A low-grade fever (99° F [37° C]) is noted when the patient is seen in the physician's office. Her pharynx is red, exudate is present, and her tonsils are swollen. The physician requests a group A streptococcal direct antigen test, and the test is negative. A follow-up culture is positive for group A streptococci 24 hours later.

Issues to consider

After reading the patient's case history, consider:

- All of the intricate processes involved in quality assurance
- How the sensitivity and specificity of a laboratory test is used in the clinical diagnosis of a disease
- How activities at each phase of the workflow (preanalytic, analytic, and postanalytic) affect the accuracy of laboratory testing
- How the prevalence of a disease in a population affects the predictive value of laboratory tests
- Why it is important to constantly validate methods and procedures used in the laboratory

Providing accurate results in laboratory testing is of the utmost importance in clinical settings and public health. The consequences of inaccurate results can be devastating because the patient's health outcomes depend on accurate test results and timely reporting for effective treatment. All phases of laboratory testing must be performed with ultimate precision. Results must be reported to the primary care provider at the time when clinical decisions regarding patient's treatment plan are to be made.

The issue of quality in the laboratory is complex. Because laboratory operations performed by various laboratory personnel involve numerous processes and procedures, a performance management and improvement system must be in place to achieve consistent, quality laboratory performance.

This chapter describes quality management and performance improvement as they apply in the clinical microbiology laboratory. It provides performance monitors and evaluation tools to assure quality performance, guidelines for establishing quality control (QC) measures, and how to document and institute corrective actions. This chapter also describes the value of test validation, clinical applications of test sensitivity, specificity, and predictive values of diagnostic tests.

Introduction to quality management system

Laboratories have always taken measures to ensure that the testing performed on patient specimens produces reliable and accurate laboratory data. This effort has been termed **quality control (QC)**. Examples of QC in the clinical microbiology laboratory are checking media and reagents with specific organisms to determine whether expected results are obtained and documenting that instrumentation meets all operating parameters before it is used to process patient samples.

Over the past few decades, however, concepts and applications of quality management have evolved. Laboratory professionals now recognize that QC is only a small part of the overall assessment of quality within the entirety of the laboratory workflow. **Quality assurance (QA)**, a process that involves monitoring all components of a system or procedure (preanalytical, analytical, and postanalytical) and implementing changes when suboptimal performance is identified, involves taking proactive measures to ensure high-quality patient care.

Even when the laboratory has effectively controlled media, reagents, and instruments, the quality of the test result is poor if the specimen was improperly collected or degraded before arriving in the laboratory and was still assayed. Suppose a specimen is labeled with the wrong patient's name; again, the media can be of top quality, the incubator temperature accurate, and the laboratory scientist very competent, but if the results are reported for the wrong patient, quality patient care management for the patients involved is absent.

Workflow

The goal of a quality management system is continuous performance improvement in laboratory processes. All

processes and procedures must be conducted correctly to ensure that the test results are accurate and reliable. Laboratory testing has become more complex. Performance improvement and quality management systems must address all areas of the laboratory operations that are systematized in a workflow.

Workflow is the series of activities that are necessary to complete a task. In the clinical and laboratory diagnosis of an infectious disease, for example, workflow may begin with the specimen collection at the point-of-care, where the clinician or health care provider sees the patient. Each step in the workflow must be completed with accuracy and precision in as short a time as possible. Workflow in the clinical laboratory, divided into three phases, preanalytical, analytical, and postanalytical,

is critical in managing performance improvement and quality management. Fig. 5.1 shows the three phases of workflow with examples of activities at each phase that can affect testing outcomes. The first phase, *preanalytical*, includes collection of samples at the patient bedside or in the clinician's office. Studies have shown that most errors occur in the preanalytical phase starting with specimen collection, handling, and patient specimen identification. Errors that occur in this phase may eventually continue down the line; hence, large institutions have added the use of technology and robotics as tools in their attempt to lessen missteps in the preanalytical phase.

The actual testing or performance of procedures on clinical samples to produce results occurs in the *analytical phase* of laboratory testing. It is important that the laboratory utilize

Fig. 5.1 Three phases of laboratory workflow with activities that affect testing outcomes.

all types of diagnostic means that provide rapid and accurate results for the clinician to make a diagnosis or other clinical decisions. The final phase is the *postanalytical* phase in which results generated by an instrument or by a laboratory practitioner (if the test is performed manually) are reviewed, verified by a technical supervisor, and reported to the requestor, typically a health care provider. It is important to realize that *preanalytical*, analytical, and *postanalytical activities* all affect quality. An outcome can be interrupted or compromised at any point in the process.

Case check 5.1

Whereas direct antigen tests for group A streptococci have improved, they are prone to false-negative results. However, specimen collection and processing could also have been performed incorrectly. As mentioned earlier, reports have shown that most errors occur in the preanalytical phase of the workflow such as during specimen collection. Monitoring of false-negative results for direct antigen tests for group A streptococci could identify a pattern requiring intervention to improve results.

The Joint Commission (TJC), the nonprofit organization that accredits health care organizations, focuses on performance measures of organizational systems that are critical to patient safety, care, and treatment. In the ever-changing health care arena, the pursuit of quality continues with concepts that integrate all aspects of health care. These concepts, called **total quality management (TQM)** and **continuous quality improvement (CQI)**, are continuous, incremental improvement processes that reflect the organization-wide philosophy that quality is everybody's responsibility. Because of the complexity of laboratory operations, performance improvement (PI) and quality management (components of TQM and CQI systems) must direct activities toward all areas that include the laboratory environment, personnel competency, QC procedures, quality of testing reagents, equipment, record keeping, and communications, to ensure quality.

Quality and performance improvement measures

Accrediting agencies such as TJC and the College of American Pathologists (CAP) emphasize PI in their accreditation checklists. The Clinical Laboratory Improvement Amendments (CLIA) also require the use of written PI policies in laboratories that include all three phases of testing. Every laboratory must have a well-established Performance Improvement Plan (PIP). To effectively improve quality and sustain reliable and reproducible laboratory performance over time, all employees must understand the entire plan and how it applies to their role within the laboratory and be active participants in the PIP.

Mission, vision, and values

The focus of a PIP is primarily on the processes, procedures, and workflow design, to resolve challenges and ensure continuous delivery of quality work and test results. Although

laboratories operate with processes and test procedures to produce results, understanding other aspects of the organizational design and structure (such as its mission, vision, and values) and their significance is also important in successfully managing and evaluating work processes.

Mission statement

Sharing the organization's mission statement with employees is an effective way to unite everyone behind the same cause. A mission statement expresses the organization's reason for existence. It describes the task, purpose, or calling—what it does and its overall intention. The mission statement supports the vision and serves to provide direction to employees, customers, and other stakeholders. In health care, this includes the patients that the health care institution serves. An example of a mission statement is at Ohio State University Wexner Medical Center: "to improve people's lives in Ohio and across the world through innovation in research, education and patient care."

Vision statement

While a mission statement defines its purpose, a vision statement describes an organization's aspirations or what it hopes to be in the future. The vision, looking into the future, is an image of the mission accomplished. As a guide when developing a vision statement, leaders try to answer the question "What will the organization look like 10 years from now if it were to accomplish all of its strategic goals?" If the mission statement provides direction and purpose to employees, the vision statement should provide inspiration and aspiration. At Mayo Clinic, the vision statement is "Mayo Clinic will provide an unparalleled experience as the most trusted partner for health care."

The laboratory must highlight the organization's vision and mission statements so personnel understand that they each have a role in the mission, and they must strive to make PI part of their daily lives to achieve the organization's vision. They must view challenges as opportunities for improvements and a chance to excel. Employees who find an organization's vision statement meaningful are more engaged, and more engaged employees are more productive.

Shared values

What serve as the moral compass for the organization's practices and its employees, guide their decision-making process, and provide the standards that guide the individual employee's behaviors are the organization's defined values shared by its employees. These core values guide the organization and its employees as they pursue new priorities and are the basis for the organization's vision and mission statements. As an example, Mayo Clinic's value statement states, "The needs of the patient come first."

Personnel competency and laboratory proficiency assessments

Competency, the ability of an individual to perform a task accurately and effectively, has played a major role in quality

management and performance improvement in the clinical laboratory. Hence, identifying the competencies for each job function is crucial and has an enormous impact in personnel competency assessment and in implementing work quality and performance improvement.

Personnel competency assessment

The CLIA (the first one was passed as the Clinical Laboratory Improvement Act of 1988 [CLIA-88]) requires that the competency of each employee be determined and verified on employment. Proof of competency must be maintained in each employee's personnel file. Competency reverification must occur annually. This requirement is to ensure that laboratory professionals are meeting the standards in test performance as required by federal regulation in order to avoid errors that could lead to harming patients. Competency assessment is different from proficiency testing under CLIA. While **competency assessment** determines the ability of laboratory personnel to perform their duties satisfactorily, **proficiency testing** (PT) assesses the ability of the laboratory to produce accurate and reliable test results by providing them with unknown samples prepared by a Centers for Medicare and Medicaid Services (CMS)-approved PT program. Proficiency testing, as it pertains to the laboratory, is discussed later in this section.

The clinical laboratory is one of the most highly regulated workplaces in health care. Laboratory personnel must meet strict quality standards, from specimen processing to assess acceptability to reporting of results. CLIA requirements expect that laboratories assign a complexity rating to all tests or analyses performed by the laboratory. In microbiology, all tests are moderately complex or highly complex. Microbiology laboratory personnel must meet certain educational requirements before they are allowed to perform at each level of complexity. Personnel competency at each level of complexity testing must be assessed and documented before they are cleared to perform tests on patients' samples independently. Competency assessment of testing personnel is required by CLIA to be completed at least semiannually during the first year the laboratorian performs tests on patient specimens and then annually thereafter. According to CLIA, an individual designated as a Technical Consultant for moderate complexity testing and the Technical Supervisor for high complexity testing are responsible for developing and administering competency assessments to personnel to ensure that they have the proficiency level required to perform laboratory testing.

A common method to administer competency testing is to give laboratory personnel samples as unknowns. Competency is determined by use of a variety of techniques, such as the following:

- Direct observations of routine patient test performance including patient preparation, if applicable, specimen handling, processing, testing; monitoring the recording and reporting of test results
- Review of worksheets
- Assessment of test performance through testing previously analyzed specimens, internal blind testing samples, or external proficiency testing samples
- Assessment of problem-solving skills with written examination

An example of a competency check-off form is shown in Fig. 5.2. Personnel competency must be assessed twice a year on all tests performed on patient samples. Proficiency samples for demonstrating competency may be purchased commercially or prepared internally. The periodic assessment of employee's proficiency on competencies identified for the employee's job role or function provides information on possible skill gaps; assists in a focused, effective training and development plan; and guides both employee and manager in the development of learning plans to help the employee fill the skill gaps.

Proficiency testing

TJC and the CLIA require that laboratories enroll in a CMS-approved proficiency testing program for each regulated analyte tested. Laboratories are required to maintain successful performance on proficiency testing. PT is an example of an external quality management assessment and allows laboratories to compare their performance to the performance of other similar laboratories participating in the same PT event (interlaboratory comparison). Unsuccessful performance is defined as a failure to achieve satisfactory performance for two consecutive or two of three consecutive testing events. When unsuccessful PT occurs, TJC will request a plan of action. If the problem cannot be resolved, an onsite evaluation may be conducted, which can affect accreditation status and force the laboratory to stop testing.

PT samples are available from several approved providers, and a list is available at the CMS website. PT samples must be assayed in the same manner as patient material, except that no PT sample shall be referred to another laboratory for analysis. A laboratory must not test PT samples on more than one instrument or by multiple methods unless that is how patient specimens are processed. In microbiology, microorganisms in proficiency tests must be identified in the same manner as clinical specimens.

Continuous education and training

A quality management and performance improvement plan may also include ongoing professional development, continuous education, and training requirements for all personnel. These **continuing education** (CE) programs may include didactic lectures on new nomenclature, emerging pathogens, or newly developed techniques. Case study presentations or training on new instrumentation are other approaches to CE of laboratory personnel. It is essential that CE programs attended by personnel are documented. Training on new instrumentation should also be documented in the individual employee's personnel competency file.

Indicators of performance improvement

Many types of monitors or indicators can be incorporated into a performance improvement program. Accrediting agencies generally make sure that a variety of types are used. Some monitors are ongoing data collections even when no problems are expected. Results are compiled and routinely evaluated. This procedure establishes a trend and makes problems easy to detect as disruptions in the trend. These are often referred to as **process monitors**.

Employee name: Carol Johnson Year 2020

Demonstrates following abilities:	Work station		
	#1 Respiratory	#2 Urine	#3 O & Ps
1. Handles specimens safely during testing, storing, and discarding	✓	✓	✓
2. Prepares specimens for analysis according to laboratory policies and procedures (parasitology and special procedure areas)	—	—	✓
3. Analyzes specimens according to laboratory procedures for the workstation; knows theory and principles of the tests being performed	✓	✓	✓
4. Clearly records all work done so that another person could take over the workstation	✓	✓	✓
5. Reports results accurately and in a timely manner	✓	✓	✓
6. Makes appropriate critical value and courtesy calls	✓	✓	✓
7. Consistently performs and records quality control and documents all remedial action	✓	✓	✓
8. Remedial action necessary (yes or no)	No	No	No

Remedial actions: _____

Date remediation completed: _____

Evaluator signature A Holbrook Date 2/11/20 (Workstation 1)

Evaluator signature L Creme Date 6/9/20 (Workstation 2)

Evaluator signature S Young Date 8/27/20 (Workstation 3)

Employee signature Carol Johnson Date 8/28/20

Fig. 5.2 Competency documentation.

Outcome monitors are measurements of the result of a process, such as complications that a patient experiences as the result of a process. Other monitors may be created in response to a suspected problem. Data may be collected for a short period to resolve a specific issue. These monitors are called **focused monitors**.

Establishing performance monitors

As an accrediting agency, TJC makes recommendations for establishing performance monitors. The recommended components for a performance monitor are to plan, design, measure, assess, and improve.

BOX 5.1 Measurable processes

Patient preparation
 Specimen handling
 Collection
 Labeling
 Preservation
 Transportation
 Communication processes
 Transfer of information
 Completeness of testing request
 Reporting timeliness
 Report accuracy
 Test appropriateness
 Patient needs and expectations
 Risk management activities
 Quality control activities

Plan: The plan is not expected to be a single-department approach. Rather, it should be a coordinated, organization-wide approach for improving patient outcomes that includes interdisciplinary collaborative actions. The plan phase is about developing an “aim statement” for the project to help stay focused and motivated. The aim statement should be precise and not too broad to ensure overall success of the project.

Design: Clear objectives are needed to describe a new process, component, or service. During this phase of the project, it is important to evaluate the “domino effect” and consider which stakeholders these potential changes can affect so that multidisciplinary discussions can take place if need be, and processes, policies, and procedures can be modified as needed.

Measure: Systematic data collection is necessary for improvements or for ongoing measurements. [Box 5.1](#) lists suggested measurable processes.

Assess: A review of the collected data should be systematic, interdisciplinary, and interdepartmental as well as statistically based using analytic tools. Internal comparisons or comparisons with similar processes in other organizations are appropriate. Guidelines for assessments might be accreditation standards, practice guidelines, or legal and regulatory requirements.

Improve: Current processes or a design of new processes may need to be redesigned. Because more opportunities are usually identified than can be acted on, priorities must be established. Priorities are often based on risk, frequency, or high-volume processes. Some of the good ideas that a team identified along the way, but are not relevant to the particular project, may be moved into the “parking lot” and saved for future projects. It is important to stay focused and disciplined so that projects are documented, changes are implemented, and results are achieved systematically and reliably.

Lean and Six Sigma in the laboratory

First developed by the Japanese automotive industry, the central idea of Lean is to minimize waste while at the same time maximizing customer value. In implementing Lean principles, the laboratory is able to create efficient processes and eliminate wastes as identified by customers.

Examples include waste of motion, materials, effort, and time. In the laboratory, standardization of work processes is a Lean opportunity. It ensures all personnel handle tasks the same way. When standard operating procedures (SOPs) are in place, errors are minimized and ultimately, patient care improves. Another example of how Lean is applied in the laboratory is in the design of space that is centered either around an activity or around a type of specimen. Such Lean design saves time and improves workflow. In the microbiology laboratory, consider where there is waste of motion or time, especially in specimen collection and transport of infectious materials.

The underlying principle of **Six Sigma (6σ)**, another tool for process improvement, is that any deviation in a process presents opportunities for errors, which then leads to product defects and customer dissatisfaction. By applying Six Sigma methodology, causes of deficiencies in the process may be identified and chances for errors can be reduced. Six Sigma (the Greek letter *sigma* is used to denote variation from standard) uses statistical methods. The organization may form an infrastructure of people who are experts in these methods.

What does a *Sigma* value mean? Simply explained, a *Sigma* value or *Sigma* level designates how often mistakes are likely to occur in a process or procedure and represents the number of errors per 1 million opportunities—the higher the Sigma, the fewer the number of errors. In the clinical laboratory, a process to be considered high quality will have to make a Sigma score of six, which is the highest level that can be achieved. That means to achieve Six Sigma, the process must not produce more than 3.4 failed QC results per 1 million. When Six Sigma methodology is applied across the laboratory workflow: preanalytical, analytical, and postanalytical. It can assist with improving accuracy and strengthening the laboratory’s QC activities.

Because medical providers rely heavily on accurate laboratory test results to confirm or reject a diagnosis, initiate therapy, or make other clinical decisions on patients, reducing the chances of errors in a laboratory test result is crucial in saving patients’ lives. Implementing quality management and process monitors like Lean and Six Sigma is appropriate in creating an environment supportive to process evaluation and performance improvement.

Problem-action form

Another approach to monitoring or documenting quality issues is a problem-action form. This approach is commonly used to document issues that are quickly resolved but could also be used for long-term monitor summation. The form is a brief statement consisting of the following information:

- Date
- Problem
- Evaluation and investigation
- Corrective action
- Outcome

The form may be signed by the person submitting it, and additional documentation may be attached as necessary. [Table 5.1](#) illustrates the use of the problem-action form.

Table 5.1 Clinical microbiology problem-action report

Date	11/15/21
Problem	A blood culture was required from a patient at the urgent care facility, but no staff member was trained to draw blood cultures. The patient had to drive from the urgent care facility to the hospital to have the blood drawn by a phlebotomist who was trained in the appropriate techniques
Evaluation	No employees at the urgent care facility have been trained to collect blood cultures. The same is true of the clinic outpatient laboratory. This is the second occurrence in about 2 months
Corrective action	Seriously ill patients should not have to travel from one facility to another to have their blood drawn. Laboratory administration was informed of this situation
Outcome	All outpatient sites will receive training and written instructions for the proper collection of blood for culture. Patients will no longer have to drive to the hospital for this service if they are already at an outpatient facility
Submitted by	M. Rausch
Attached documentation?	No

Learn from defect

More recently, another tool, *Learn from Defect*, is being used widely to evaluate risks and eliminate them as much as possible to prevent a similar event from affecting other patients in the future. The tool intends to provide a methodical and structured approach to ensure that every component of the process is assessed, and nothing is left to chance. When *Learn from Defect* is applied in a performance improvement plan, a cross-functional team is tasked in the risk assessment and development of a corrective plan. With *Learn from Defect*, the cross-functional team will do the following:

1. Provide a concise, objective, factual description of the event in question.
2. Carefully review all of the factors that may have contributed to the event. Then, determine which factors contributed negatively to the event and which factors contributed positively to the event. Negative factors are those that potentially may bring harm to the patient; positive factors limit such harm. Rate the most important factors that contributed to the event.
3. Outline how to limit and eliminate the negative factors. Decide what will be done and who will lead the interventions to eliminate those factors.
4. Determine how to evaluate the new process to ensure that it is working as designed, risk is reduced, and the process is sustained.

The customer concept

Like any business, laboratories must focus on the **customer concept**. Who are the customers, and what is a customer's perception of quality? Patients are not the only customers.

Anyone who looks to the laboratory for a service is a customer. Physicians, nurses, insurers, and patients are all customers. Each customer may view quality differently and may have different expectations. Laboratory professionals may judge quality in terms of accuracy, a physician may view it as turnaround time, a patient may view it as compassion and relief from pain, and an insurance company may view it as cost-effectiveness. Customer satisfaction must be surveyed to determine perceptions.

Fixing the process

When patient outcome is less than desirable, the process must be evaluated and corrected. The focus is on the process, not on an individual. The primary rule to follow is to refrain from finger pointing or fault finding. Preanalytic and postanalytic activities usually take place outside the laboratory and require **cross-functional teams** to evaluate and correct the process. Department representatives can easily become defensive and territorial. Barriers to cooperation must be removed, and the easiest way to achieve it is to remain collegial, professional, and patient-centric at all times.

Cross-functional teams must include a trained *facilitator*. Facilitators are most effective when they have no vested interest in the process being evaluated. The facilitator's role on the team is to use problem-solving training and experience to help the team brainstorm and stay on track. In the formation of a cross-functional team, those who are actually doing the work must be represented; the team should not consist solely of supervisory personnel. If the issue is transportation of specimens, for example, the team should include, at minimum, a transporter, a specimen processor, a staff nurse, a medical student or physician representative, appropriate supervisory personnel, and a facilitator. The most accurate and meaningful brainstorming ideas usually come from the people who perform the tasks, not from those who designed the process. When is a process fixed? It is not fixed just because the reason something went wrong is explained. It is fixed only when the problem is prevented from happening again and the new process is reliably sustained.

Benchmarking

A benchmark is a reference point. **Benchmarking** is seeking an industry's or profession's best practices to imitate them and improve. Benchmarking was initially practiced in business and industry but has now become an important part of a hospital quality management program. It is done willingly and openly. There are two main types of benchmarking: business or operations benchmarking and quality benchmarking.

Operations benchmarking

A hospital can join a large group of other hospitals that all share operating statistics. Productivity and cost-effectiveness are two large categories commonly used in a benchmarking comparison. The best performers in a group of hospitals are highlighted. Hospitals can individually and anonymously see where they are by comparison with other hospitals' statistics and then contact the best performers to evaluate their differences. A code of conduct that includes ethics and etiquette is followed when

benchmarking is performed. Although hospitals generally benchmark other hospitals, they often incorporate lessons learned from other successful industries.

Quality benchmarking

Examples of quality benchmarking are commercially purchased monitors. The CAP created a national PI assessment program called *Q-probes*. Laboratories throughout the country subscribe to an annual series of monitors. At least one of these monitors each year has a microbiology focus. *Q-probes* have covered topics such as adequacy of sputum cultures, turnaround time for spinal fluid Gram-stain results, blood culture contamination rates, and appropriateness of ordering patterns for stool specimens. The method of data collection is precisely outlined, and all worksheets and data forms are provided. Information is returned to subscribers in a manner that enables institutions to perform benchmarking.

Quality control in the microbiology laboratory

QC is a small but important part of TQM and CQI, and as such, it contributes to the organizational goal of providing quality patient care. All QC activities that take place must be recorded to prove their existence and create a traceable record that can be used in case troubleshooting or investigation is required. All record sheets must list tolerance limits, when applicable, so the person recording the results will know whether the value being recorded is acceptable. Corrective action must also be recorded when any measurement falls outside a tolerance limit. The responsibility for QC may rest mainly with one person, but in reality everyone must participate if a program is to be successful. A QC program for a microbiology laboratory must include procedures for control of temperature, equipment, media, reagents, and antimicrobial susceptibility testing.

Temperature

Daily temperature checks are required on all temperature-dependent equipment:

- Incubators
- Heating blocks
- Water baths
- Refrigerators
- Freezers

Incubator and refrigerator thermometers are easier to read if they are permanently immersed in glycerol. This helps prevent temperature fluctuations when the door is opened to read the thermometer. Before use, each thermometer must be checked against a reference thermometer from the National Institute of Standards and Technology (NIST), formerly the National Bureau of Standards (NBS). The most efficient method is to check a large batch of thermometers at the same time and at the temperature ranges likely to be used. A common practice in clinical microbiology is to test all thermometers at -20°C , 2°C to 8°C , 37°C , and 56°C . The NIST

thermometer comes with certification papers that list correction factors to be used in various temperature ranges. These correction factors are applied to all values obtained with individual laboratory thermometers. Laboratories arbitrarily determine the acceptable temperature variance. For most routine work, thermometers that differ by 1°C or more from the reference thermometer are discarded.

Thermometer calibration

Thermometers are calibrated by batch on arrival in the laboratory. Procedure 23 in Appendix D on Evolve outlines the calibration procedure. Once the thermometer passes calibration and is placed in use, repeated calibration of the thermometer should not be necessary. Alternatively, thermometers already checked against an NIST thermometer can be purchased. Certificates of calibration should be kept for the life of the thermometer or until the expiration date on the certificate; after that date, the thermometer can be recalibrated or discarded. Thermometers should be checked daily to ensure that gas bubbles have not been introduced into the liquid, making reading the temperature difficult. Gas bubbles can be eliminated by centrifugation or by placing the thermometer at a high or low temperature.

Equipment maintenance

Equipment used in the clinical microbiology laboratory must be tested for proper performance at intervals appropriate for each item or per the manufacturer's recommendation. This process may involve checking the percentage of CO_2 in an incubator daily or measuring the revolutions per minute of a centrifuge twice a year. How often the instrument or equipment needs to be calibrated must be determined and is based on its stability or the manufacturer's recommendation. In newly installed equipment, a system for recording the use of parts and supplies, performance verification, frequency for calibration, and proper operation must be developed. [Table 5.2](#) gives examples of some laboratory equipment, the type of testing done, and the frequency of testing.

Table 5.2 Frequency of equipment testing

Equipment	Test type	Frequency
Incubator	Temperature, CO_2	Daily
GasPak jar	Anaerobiosis, catalyst-heated	Each use
Anaerobe chamber	Anaerobiosis, humidity, temperature	Daily
Biological safety cabinet	Air flow (done by specialist)	Annually or any time hoods are moved
Centrifuge	Check rpm	Every 6 months
Microscope	Cleaned and adjusted	Four times per year or as needed
Autoclave	Temperature Spore testing	Each load Weekly
Balance	Accuracy of weights	Annually

rpm, Revolutions per minute.

A **preventive maintenance** program must be established as an additional control measure. Scheduled maintenance, which may include daily, weekly, and monthly maintenance activities, must be instituted and assigned to personnel responsible for the maintenance program. Preventive maintenance performed on equipment generally involves tasks such as oiling and cleaning, replacing filters, and recalibrating instruments. Keeping an instrument in best condition and functioning at the proper level will extend its lifetime. Fig. 5.3 shows an example of a preventive maintenance log sheet.

Media quality control

Each batch of user-prepared media must be tested for sterility and performance as part of media QC. Documentation must show that the media support the growth of appropriate microorganisms and, if appropriate, inhibit growth of specific microorganisms or produce the correct biochemical response. Records must be maintained for 2 years. The criteria

are established by the **Clinical and Laboratory Standards Institute (CLSI)** and are listed in document M22-A2.

QC for user-prepared medium includes the following:

- All user-prepared media must be tested before use.
- Each medium must be tested with organisms expected to grow or give a positive reaction as well as with organisms expected not to grow or to produce a negative reaction.
- The medium should be tested for sterility and pH.
- The organisms selected for QC should represent the most fastidious organisms for which the medium was designed.
- Testing techniques should be different for primary plating media than those for biochemical or subculture media. Primary plating media should be tested with dilute suspensions of organisms, whereas biochemical media can be tested with undiluted organisms.
- QC testing should be performed according to CLSI recommendations.
- Expiration dates must be established.

Fig. 5.4 shows a log sheet used for testing media prepared in-house.

Commercially prepared media are tested by the manufacturer. The laboratory must obtain a statement of QC from the manufacturer for all media that the laboratory will not retest. This certificate must be retained for as long as the

laboratory uses the specified media. Nevertheless, certain types of media must be retested by the user. Examples of media that require retesting are chocolate agar, selective media for pathogenic *Neisseria*, and *Campylobacter* media. Fig. 5.5 lists specialty commercially prepared media that have been retested by the laboratory. A list of all media

requiring retesting can be found in CLSI document M22-A2. In addition, the laboratory must examine all commercially prepared media for the following:

- Moisture: Plates should be free from moisture before use but should never show signs of drying around the edges.
- Sterility: Plates should be free from contaminants.
- Breakage: Petri dishes should not be cracked or broken.
- Appearance: Blood-based plates should not show signs of hemolysis, and any other plate that deviates from the normal color should not be used. Any deterioration should be reported to the manufacturer.

Results of media observations must be recorded along with the lot numbers. Fig. 5.6 shows an example of a media observation log, which helps ensure that good-quality media are used on all patient samples. Corrective action must be taken when a medium does not meet standards. This can be documented on a separate record known as a *media corrective action log* (Table 5.3).

Reagent quality control

With few exceptions, reagents should be tested on each day of use with both positive and negative controls. Reagents that are documented to have consistent and dependable results may be tested less frequently. Some reagents may be tested more than once a day. Reagents that are opened and used

repeatedly should be checked daily for sterility. Examine and follow the manufacturer's package insert for recommended QC requirements.

QC should be performed and documented on all staining procedures at least daily. For the Gram stain, known organisms from the American Type Culture Collection (ATCC) include gram-positive bacteria (*Staphylococcus aureus* ATCC 25923) and gram-negative bacteria (*Escherichia coli* ATCC 25922). All staining procedures must be verified before patient results can be released. Some examples of reagents that should undergo QC in microbiology are as follows:

- All stains
- β -Lactamase
- Catalase
- Coagulase
- Germ tube solution
- Hippurate
- Kovacs reagent
- Nitrate
- Optochin
- Oxidase
- L-Pyroglutamyl- β -naphthylamine
- Typing sera
- Voges-Proskauer broth
- X and V strips

Fig. 5.7 Various testing methods that can be performed daily at an individual workstation. Shown is an example of a 2-week workstation quality control. ND, Not done.

Antimicrobial susceptibility quality control

The CLSI provides guidelines for QC of susceptibility testing. The recommended control organisms are specific strains from the ATCC (Table 5.4). In addition to the organisms listed in Table 5.4, fastidious organisms such as

Haemophilus influenzae and *Neisseria gonorrhoeae* are tested to ensure that the best possible results are obtained when the same type of isolates recovered from patient samples are tested.

Careful storage of degradable supplies following the manufacturer's recommendations and precision in the

Table 5.4 Recommended control organisms for susceptibility testing

Organism	Susceptibility test(s)
<i>Escherichia coli</i> , ATCC 25922	Gram-negative agents
<i>Escherichia coli</i> , ATCC 35218	β -Lactamase inhibitor agents
<i>Staphylococcus aureus</i> , ATCC 25923	Gram-positive agents—Kirby-Bauer test
<i>Staphylococcus aureus</i> , ATCC 29213	Gram-positive agents—minimal inhibitory concentration
<i>Pseudomonas aeruginosa</i> , ATCC 27853	Monitors Ca^{2+} and Mg^{2+} content in media ^a
<i>Enterococcus faecalis</i> , ATCC 29212	Monitors thymidine content in media ^b

^aAs Ca^{2+} and Mg^{2+} concentrations increase, *P. aeruginosa* becomes more resistant to the aminoglycosides.

^bIncreases in thymidine concentration cause false resistance to certain drugs, such as sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole.

implementation of recommended procedures are mandatory to obtain accurate and reproducible susceptibility results. In any susceptibility system, many variables can affect the accuracy of results, including the following:

- Antimicrobial agent potency
- Agar depth (Bauer-Kirby test)
- Evaporation (microtiter dilution)
- Cation content
- pH
- Thymidine content
- Instrument failure
- Inoculum concentration
- Temperature
- Moisture (Bauer-Kirby test)
- Difficulty in determining end points

Susceptibility testing of control organisms is usually conducted daily until precision can be demonstrated with 20 or 30 consecutive days of susceptibility testing using CLSI guidelines. The control organism results must be evaluated before end points are determined on patient isolates. Minimal inhibitory concentrations (MICs) must be within one log dilution of the expected MIC according to CLSI guidelines. Once the 20- or 30-day evaluation has been accomplished, QC organisms may be tested weekly instead of daily. All results from the 20- or 30-day evaluation should be kept as long as the antimicrobial agent is used or for at least 2 years after discontinuation of use of the agent.

Use of stock cultures

To operate a QC program, all laboratories must maintain stock cultures available from many sources:

- Commercial
- Patient isolates
- Proficiency testing isolates
- ATCC

When QC testing appears to have failed, it is usually the stock culture rather than the test itself that has failed. With

repeated subculturing, organisms can mutate. For best results, a stock culture should be grown in a large volume of broth and then divided among enough small freezer vials to last a year. With this technique, a new vial can be removed from the freezer weekly so organisms do not have to be subcultured continually. Before testing, an organism should be subcultured twice after thawing to return it to a healthy state. Media selection for freezing is at the discretion of individual laboratories, but the media should not contain carbohydrates. If organisms use carbohydrates while being maintained, the acid products that result might kill the organisms over time. The following are popular media choices for stock cultures:

- Schaedler broth with glycerol
- Skim milk
- Chopped meat (anaerobes)
- Tryptic soy agar deeps (at room temperature)
- Cystine tryptic agar without carbohydrates

Another popular method of storage is the use of storage beads. Storage beads are contained in a vial containing 1 mL of thioglycolate broth. After the vial has been inoculated with the organism, the broth is removed, and the vial with the beads is stored at -70°C . The advantage of this system is that a single bead can be removed without the entire vial being thawed. Although this form of storage is more convenient, it is more expensive than those mentioned earlier. Organisms should be frozen at -70°C ; alternative storage methods include freezing in liquid nitrogen and lyophilization.

Quality control manual

All policies and procedures for QC should be written in a QC manual and be available to employees at the workstation. The manual must be reviewed, signed at least annually, and revised as needed by a supervisor. If major changes are made to any of the policies and procedures or if new policies and procedures are introduced, a review and approval by the medical directors are required.

Individualized quality control plan

Individualized quality control plan (IQCP) is the policy name for an alternative CLIA QC program that provides laboratories with the opportunity for equivalent quality testing. Laboratories have the options of following CLIA regulations or developing an IQCP. The three required parts of an IQCP are risk assessment, QC plan (QCP), and quality assessment. An IQCP will not necessarily reduce QC, but it does permit laboratories to develop their own QC protocols that recognize technology included in laboratory test systems. An IQCP allows laboratories to customize QC on the basis of unique environments, test systems, and so on. The laboratory must document that the IQCP is based on evidence collected in-house but can incorporate test system manufacturers' quality certificates.

If a laboratory chooses to implement an IQCP, the laboratory medical director must review and approve the IQCP. Once in place, the IQCP monitors laboratory testing and defines investigation and problem solving, leading to adjustment to the IQCP as needed. In microbiology, for example, visual quality checks of media along with

manufacturers' quality certificates could be considered in the risk assessment. A microbiology laboratory could adapt an IQCP that applies to all media or use separate plans for individual media. In the case of laboratory instrumentation (e.g., a continuous-monitoring blood culture system), the laboratory director might choose to use the manufacturer's instructions for QC if they meet or exceed CLIA regulations. The laboratory must document that the test system results support the number and frequency of the QC specified in the IQCP. To ensure ongoing effectiveness of the IQCP, it must be reviewed annually. CAP published a desired IQCP Annual Evaluation Form that is widely adapted for this purpose.

Evaluating and interpreting diagnostic laboratory tests

Recently, tests in clinical microbiology have shifted toward the detection of antigens, protein profiles, and nucleic acids. Although culture remains the gold standard or reference method for most diagnostic purposes, newer, nonculture detection assays offer simplicity and speed for detection of the causative agent. In addition, in these assays the immune status of the patient does not affect test results, as can occur when detecting antibodies. Nonculture, direct antigen detection tests are designed for use in the physician's office and, as such, are easily performed by non-laboratory personnel. Because the test results are available quickly, the physician can make an informed decision regarding patient treatment.

These tests can, however, be misused or their results misinterpreted. Tests with a high sensitivity and specificity may be promoted as extremely reliable diagnostic tests. In certain clinical situations, such tests may not add meaningful information to the diagnosis. It is important to understand the value and limitations of diagnostic tests for optimal health care.

Analytic analysis of tests

The following terms relate to the actual test and are not used in the critical evaluation of a test in the clinical setting. Analytic sensitivity and specificity should not be confused with clinical sensitivity and specificity.

Analytic (technical) sensitivity and specificity

Sensitivity

The analytic sensitivity of a test refers to its ability to detect a particular analyte or small change in its concentration. **Analytic sensitivity** is usually defined at the 95% confidence level ($\pm$ two standard deviations) and may be referred to as the *detection limit*. In microbiology, the **detection limit** may be correlated to the number of colonies in the culture or to the lowest quantity of antigen or antibody a test can detect. For example, the enzyme immunoassay (EIA) is more sensitive than the precipitation test in detecting antibody. The EIA can detect lower concentrations of antibody.

Specificity

A test's **analytic specificity** refers to its ability not to react with substances other than the analyte of interest. In other words, it detects only one analyte.

Accuracy

The degree of conformity of a measurement to a standard or a true value is its accuracy. It is a measure of analytic capability. For example, with the performance standards for antimicrobial disk susceptibility tests, a mean value of several observations is compared with a predetermined standard value or range. If the mean (or range) of control limits found in standard tables is exceeded, a technical systematic error (variation) exists that might lead to misinterpretation of the test results.

Accuracy is a function of two characteristics: precision and bias. **Precision** is the measure of exactness or the degree of refinement with which a test is performed. It is the dispersion of repeated observations caused by random errors. The precision (reproducibility) of a test is usually monitored by the standard deviation. A larger standard deviation indicates greater dispersion of measurements and less precision. Means of the range (maximum to minimum) within sets of observations can provide a rough measure of precision. **Bias** is the difference between this measured value and the true value of the analyte being measured. It is the mean difference of test results from an accepted reference method caused by systematic errors. Precision and bias are determined by studies wherein several investigators or laboratories perform repeated testing of several specimens of known values. The test results are then analyzed by statistical methods to determine the test's precision and bias within and among laboratories.

Clinical analysis of tests

Clinical (diagnostic) sensitivity

Clinical (diagnostic) sensitivity is the proportion of positive test results obtained when a test is applied to patients known to have the disease; thus it is the frequency of positive test results in patients with the disease (true-positive [TP] results). For example, if 100 patients who have gonorrhea are tested for that disease and the test yields positive results in 95 patients and negative results in the other 5, then the sensitivity of the test is 95%, $(95/100) \times 100$. Five of these 100 patients had false-negative (FN) test results.

The highest clinical sensitivity is desired when a disease is serious and when false-positive (FP) results will not lead to serious clinical or economic problems. Sensitivity is expressed as a percentage:

$$\frac{\text{Number of TP results}}{\text{Number of TP} + \text{FN results}} \times 100$$

The sensitivity of a particular test does not change if the test is performed correctly. The sensitivity is determined by multicenter clinical trials whereby the test results, obtained

by the test being performed according to a specific protocol, are compared with results from a reference method. In microbiology, the reference method is usually culture, which in many cases is not absolute. Thus the reported sensitivity for a certain test may differ among laboratories. Evaluating new diagnostic tests is difficult because of imperfect reference methods.

Clinical (diagnostic) specificity

Clinical (diagnostic) specificity is the proportion of negative results obtained when a test is applied to patients known to be free from the disease. Thus it is the frequency of negative test results in patients without the disease (true-negative [TN] results). For example, if 100 patients without gonorrhea are tested for that disease and the test yields negative results in 90 patients and positive results in the other 10, then the specificity of the test is 90%, $(90/100) \times 100$. Of these 100 patients, 10 had false-positive test results.

The highest clinical specificity is desired when the disease is serious but not treatable, when disease absence has psychological or public health value, or when FP results might cause serious clinical or economic problems. Specificity is expressed as a percentage:

$$\frac{\text{Number of TN results}}{\text{Number of TN} + \text{FP results}} \times 100$$

As with sensitivity, the specificity does not change if the test is performed correctly. The specificity is also determined by clinical trials whereby the test results are confirmed by a more definitive test or procedure.

Operational analysis of tests

Although sensitivity and specificity do not change for a given test, the prevalence of the disease and the positive predictive value (PPV) and negative predictive value (NPV) of a test do change. In clinical medicine, these parameters are extremely important to know when one is evaluating a particular test result.

Incidence of disease

Incidence is the number of new cases of a disease over a period (e.g., months, years) and is a measure of events. The incidence rate is usually calculated by dividing the number of infections acquired during a given period by the population at risk for that same time.

Prevalence of disease

Prevalence is the frequency of a disease at a designated single point in time in the population being tested. For example, the prevalence of strep throat in children attending daycare centers will be higher than the prevalence in children who do not attend such centers. The relationship between prevalence (P) and incidence (I) can be seen in the equation

$$P = I \times D$$

where D is the duration of disease from onset (diagnosis) to termination. For chronic diseases, such as cancer, the prevalence is greater than the incidence; for acute diseases, such as gonorrhea, the prevalence is less than the incidence.

The role prevalence plays in determining the PPV and NPV of a test can be seen in the formulas in the next section. To interpret test results properly, laboratorians and physicians must have an understanding or estimate of the prevalence of the disease in the population being tested. Prevalence can be estimated on the basis of clinical experience and information provided by local and state health departments as well as information periodically provided by the Centers for Disease Control and Prevention.

Predictive values of tests

A diagnostic test has a PPV and an NPV. Three elements are needed to compute the PPV and NPV of a test: the sensitivity and specificity of the test and the prevalence of the disease being tested. The formulas for calculating PPV and NPV are commonly referred to as **Bayes's theorem**, which was published posthumously in 1763.

The **predictive value** of a test is the probability that a positive result (**positive predictive value** [PPV]) accurately indicates the presence of an analyte or specific disease, whereas a negative result (**negative predictive value** [NPV]) accurately indicates the absence of an analyte or specific disease. Predictive values vary significantly with the prevalence of the disease or analyte unless the test is 100% sensitive (for NPV) or specific (for PPV).

Positive predictive value

The PPV is computed as follows:

$$\text{Number of TP results} = (P)(Se)$$

$$PPV = \frac{(P)(Se)}{(P)(Se) + [(1 - P)(1 - Sp)]} \times 100$$

where P is the prevalence of the disease being tested, Se is the sensitivity of the test, and Sp is the specificity of the test. The number of TP plus FP results equals $(P)(Se) + [(1 - P)(1 - Sp)]$.

Negative predictive value

The NPV is computed as follows:

$$\text{Number of TN results} = (1 - P)(Sp)$$

$$NPV = \frac{(1 - P)(Sp)}{(1 - P)(Sp) + (1 - Se)P} \times 100$$

where P is the prevalence of the disease being tested, Se is the sensitivity of the test, and Sp is the specificity of the test. The number of TN plus TP results equals $[(1 - P)(Se)] + [(1 - Se)(P)]$.

Example

To illustrate the concepts of predictive values, consider a diagnostic test that has a sensitivity (Se) of 92% and a

specificity (Sp) of 95%. In a primary care hospital in which the prevalence of the disease being tested for is 1%, the PPV of the test is only 15.7%. This is calculated with the following equation:

$$\text{PPV} = \frac{(0.01)(0.92)}{(0.01)(0.92) + (1 - 0.01)(1 - 0.95)} \times 100 = 15.7\%$$

The primary care provider has only 15.7% certainty that a patient with a positive test result actually has the disease. If, however, the same test is used in a tertiary care hospital in which the prevalence of the disease is 50%, the PPV increases to 95% (calculated with the same equation). The primary care provider in this case has 95% certainty that a patient with a positive test result actually has the disease. Therefore the prevalence of the disease has a great influence on the predictive value of a test.

Clinical applications of positive and negative predictive values

Group A streptococci testing of throat samples

Acute pharyngitis is one of the most common conditions seen by primary care providers. Although most of the infections are caused by viruses, about 15% of cases have a bacterial cause, usually group A β -hemolytic streptococci (*Streptococcus pyogenes*). To test for this organism, 28 million to 36 million throat cultures are performed annually in the United States.

Approved nonculture tests for use in the private office setting are available to evaluate patients with acute pharyngitis for the presence of group A streptococci. Compared with throat culture, the reported sensitivities and specificities of these tests differ considerably. Sensitivities range from 70% to 94%. Specificities have less variation, from 90% to 99%. Although speculative, explanations for such variations may be the difficulty in obtaining an adequate throat sample, especially in children, and the use of imperfect culture methods as standards.

Assuming that a certain test for group A streptococci has reported a sensitivity and specificity of 90% and 98%, respectively, and that the estimated prevalence for streptococcal infection in acute pharyngitis cases is 5%, a typical value for adult populations, the PPV and NPV would be 70.3% and 99.5%, respectively. With a positive test result, approximately a 30% (100%–70.3%) chance exists that the patient does not have a streptococcal infection (FP). If the test result is negative, a greater than 99% chance exists that the patient is not infected. If the prevalence in the population being tested increases to 15%, a typical value for childhood populations, the PPV increases to 88.8%, but the NPV decreases slightly to 98.2%. Because the NPV is less affected by the prevalence

compared with the PPV, the NPV is generally more accurate in predicting the absence of a disease than is the PPV in predicting the presence of a disease. However, if the sensitivity is low, this will adversely affect the results of the NPV.

Direct detection of *Chlamydia trachomatis* in urethral and cervical specimens

Chlamydia is a common sexually transmitted disease (STD) in the United States, with estimates of 3 million to 5 million new cases occurring annually. Many infected individuals are asymptomatic, and proper diagnosis and treatment are essential to prevent the spread of disease and associated complications.

C. trachomatis is an obligate intracellular parasite that requires living cells for cultivation. Several days are necessary to obtain results, and the sensitivity of the culture is only about 85%. As a result, nonculture methods, such as EIA, immunofluorescence (IF), and deoxyribonucleic acid (DNA) probes, are widely used. Each has a considerable variance in reported sensitivities and specificities, most likely because of the nature of the organism and the imperfect culture standard with which the results are compared. In addition, each test requires specialized equipment that must be maintained and calibrated.

Table 5.5 shows the PPVs and NPVs for the IF and DNA probe tests applied directly to cervical samples in a population of patients in an obstetrics and gynecology clinic in whom the prevalence of chlamydial cervicitis was estimated to be 5%. The sensitivities and specificities for the two tests are similar, but the PPV is better for the DNA probe test. Thus patients with positive results of the DNA probe test are more likely to have chlamydial cervicitis than those with positive results of the IF test. On the other hand, both tests identify patients with negative test results as not having chlamydial cervicitis with a high degree of certainty (99.5%).

Table 5.5 also shows the predictive values if the same tests are used in an STD clinic in which the prevalence of chlamydial cervicitis is estimated to be 30%. The PPVs increase significantly, especially for the IF test, and both tests would function well as diagnostic tools. The NPVs drop for both tests, however, to 95.8%. Thus approximately 4% of patients with negative test results could be infected with *C. trachomatis*; this rate may not be acceptable given the nature of the disease.

Efficiency of tests

The efficiency of a test indicates the percentage of patients who are correctly classified as having disease or not having disease. The efficiency is calculated with the following equation:

$$\text{Efficiency} = \frac{(\text{TP} + \text{TN})}{(\text{TP} + \text{FP} + \text{TN} + \text{FN})} \times 100$$

Table 5.5 Comparison of immunofluorescence and DNA probe tests to detect chlamydial cervicitis^a

Test	Sensitivity	Specificity	5% Prevalence		30% Prevalence	
			PPV	NPV	PPV	NPV
IF probe	90.0	98.0	70.3	99.5	95.1	95.8
DNA probe	89.8	99.5	90.4	99.5	98.7	95.8

^aPPV and NPV were computed with equations (see text). All values are given in percentages.

IF, Immunofluorescence; NPV, negative predictive value; PPV, positive predictive value.

where *TP* is the number of patients with TP results, *TN* is the number of patients with TN results, *FP* is the number of patients with FP results, and *FN* is the number of patients with FN results. The Case in Point illustrates the importance of reflex testing, performing an additional test on the basis of the result of another test.

Case check 5.2

The Case in Point illustrates the importance of reflex testing, performing an additional test based on the result of another test. Knowing the sensitivity, specificity, PPV, and NPV of a diagnostic test can lead to improved health care. Because the sensitivity of many rapid streptococcal tests is relatively low (90%) and the proportion of acute pharyngitis cases caused by group A streptococci in children is high (15% to 30%), negative results of rapid tests in children between 5 and 15 years of age should be confirmed by a throat culture. The laboratory in this case enacted the protocol to confirm all negative results in children with a throat culture. It is not necessary to confirm negative results in adults because of a lower prevalence in this population.

Choosing a laboratory method

Once an institution has made the decision to offer a new test, the next step is generally for the laboratory to select the method (Fig. 5.8). The following are some steps that may be followed when deciding on the method:

1. Define the purpose for which the method is used.
Common purposes for tests include:
 - **Screening:** Screening is used for testing asymptomatic populations of patients. Generally, screening tests have high clinical sensitivity and NPV. Positive results with such tests generally require confirmation by a more specific test. The primary purpose of screening is to identify early stages of a disease or health problem to implement treatment.
 - **Surveillance:** Surveillance is a systematic process of identifying, collecting, analyzing, summarizing, and evaluating data about specific diseases or health problems. A large population of individuals are tested; however, the test results are not necessarily returned to the individuals. The data are used by public health officials. Cumulative information is provided to health care providers and the public.
 - **Confirmation:** Confirmation is used after a positive screening result has been obtained to ensure the accuracy of the initial result. Specificity and PPV are generally the considerations for such tests.
 - **Diagnosis:** Diagnosis is used for the evaluation of those suspected of having a given disease state or characteristic.
2. Decide which type of analyte (e.g., organism, antigen, nucleic acid) is to be detected.
3. In conjunction with the end user of the test (e.g., the physician) and information from steps 1 and 2, determine the medical usefulness of the test (e.g., to improve patient care, to shorten hospitalization time).

4. Survey the technical and medical literature for performance claims of various methods. When reviewing the literature, confirm that the method described is actually the test to be evaluated in the laboratory.
5. Other considerations include:
 - Cost
 - Practicality
 - Specimen requirements
 - Quantities of reagents and controls needed for the test
 - Shelf life of reagents and controls before and after opening
 - Availability of supplies, service, and technical support
 - Possible safety hazards
 - Whether the reference range is appropriate for that test and how it will be determined for that institution
 - Whether new equipment needs to be purchased to perform the test
6. Perform an in-house verification. Verification of a test serves to establish that the performance parameters of the test are satisfactory. The result of test verification should indicate one of three possibilities:
 - The test is acceptable for routine use.
 - Further verification studies are required.
 - The test is unsuitable for routine use until its performance parameters can be verified.

Test verification records must be kept for at least 2 years. However, it is good laboratory practice to maintain the records for as long as the test is in use.

Test validation

Verification of a test does not provide ongoing assurance that the test is continually performing as expected. **Test validation** is the ongoing process that provides information that a test is performing correctly. The components of validation are QC, proficiency testing, verification of employee competency, and instrument calibration. The results of the validation indicate one of three possibilities:

1. The test continues to be acceptable.
2. Further investigation is warranted.
3. Immediate corrective action must be undertaken, and the test must be considered unsuitable for routine use until it can be validated.

Lot numbers and expiration dates should be documented for all reagents and materials used in the validation process. Records of validation should be kept for at least 2 years. Validation should be done frequently enough to ensure the continual correct performance of tests. In most cases, following the manufacturer's guidelines and requirements of the regulatory or accrediting agencies will provide this assurance.

New laboratory tests and old ones should always be validated. Understanding and using the concepts of predictive values and the effect of prevalence on those values are important for the proper use of a test and interpretation of the results. The development of rapid nonculture tests for detecting infectious diseases makes the use of these concepts even more important. A test result can no longer be

Fig. 5.8 Choosing a laboratory method. PPV, Positive predictive value. (Modified from Clark, R. B., et al. [2009]. *Cumitech 31 A, Verification and validation of procedures in the clinical microbiology laboratory*. In S. E. Sharp (Ed.). Washington, DC: ASM Press.)

considered simply positive or negative but must be interpreted in view of the concepts presented in this chapter. When test results are interpreted properly, better patient care and outcomes are achieved.

POINTS TO REMEMBER

- Quality patient care is directly attributed to the quality of all of the processes involved in that care.
- The laboratory can ensure reliability of laboratory data through the implementation of an active QA program.
- Performance improvements and performance measurement allow organizations to monitor their performance continually and provide opportunities to improve.
- Customers must be considered in quality assurance because all customers will have their own perception of what quality means.
- When outcomes are less than desirable, the entire process must be reviewed and may require cross-functional teams and a trained facilitator to achieve the desired outcome.
- Lean is to minimize waste while at the same time maximizing customer value.
- Six Sigma's goal is to improve quality by reducing variation in any given process and therefore reduce errors in that process.
- Analytic specificity of a test is its ability not to react with substances other than the analyte of interest.
- Clinical or diagnostic specificity is the proportion of negative test results in patients without disease (true-negative results).
- Clinical or diagnostic sensitivity is the proportion of positive test results in patients with disease (true-positive results).
- Incidence is the number of new cases of a disease over a period; prevalence is the frequency of a disease at a designated single point in time.
- Predictive values are influenced by the prevalence of the disease or analyte unless the test is 100% sensitive (for NPV) or specific (for PPV).

LEARNING ASSESSMENT QUESTIONS

1. Which of the following terms refers to checking media and reagents with specific organisms to determine whether expected results are obtained?
 - a. Preventive maintenance
 - b. Quality control (QC)
 - c. Performance improvement (PI)
 - d. Total quality management (TQM)
2. Which of the following characteristics describes the process of performance improvement (PI)?
 - a. It involves only preanalytic activities.
 - b. It is measured by patient outcome.
 - c. It singles out individuals with poor performance.
 - d. It is enhanced by understanding customer perception.
3. The laboratory must perform quality control (QC) on all of the following media except which one?
 - a. Complex media
 - b. Media made by the laboratory
 - c. Media with a history of failure
 - d. All media obtained from a commercial source
4. Which of the following describes the correct way to select organisms for QC?
 - a. They should represent the most fastidious organisms for which the medium was designed.
 - b. They should be organisms that will grow most easily.
 - c. They should be immediately removed from the freezer.
 - d. Streaking should be done only once after their removal from the freezer.
5. Susceptibility tests must be quality controlled daily except when which of the following is the case?
 - a. An automated system is in use.
 - b. Controls have been in an acceptable range for 6 months.
 - c. Precision is demonstrated for 20 or 30 consecutive days.
 - d. A new antimicrobial agent is added.
6. Which of the following mandates annual employee competency testing?
 - a. Clinical and Laboratory Standards Institute (CLSI)
 - b. Clinical Laboratory Improvement Act of 1988 (CLIA-88)
 - c. National Institute of Standards and Technology (NIST)
 - d. American Type Culture Collection (ATCC)
7. A problem-action form should contain which of the following information?
 - a. Date and problem
 - b. Evaluation and corrective action
 - c. Outcome
 - d. All of the above
8. What is the term for performance improvement (PI) monitors created in response to a specific issue?
 - a. Focused monitors
 - b. Process monitors
 - c. Outcome monitors
 - d. Multitask monitors
9. Who is defined as a customer in the laboratory?
 - a. The patient
 - b. The physician and nurse
 - c. The insurance company
 - d. All of the above
10. What is The Joint Commission (TJC) initiative to monitor performance measurement?
 - a. Performance improvement (PI)
 - b. Total quality management (TQM)
 - c. Q-Probes
 - d. Continuous quality improvement (CQI)
11. Which of the following refers to the ability of a test to detect a particular analyte?
 - a. Analytic specificity
 - b. Analytic sensitivity
 - c. Efficiency of tests
 - d. Test validation
12. Using the formula provided in the chapter, determine the positive predictive value (PPV) for a *Chlamydia* test in a population in which the prevalence of the disease is 15%. The sensitivity and specificity of the test are 95% and 98%, respectively.
13. If 100 individuals without syphilis were tested for the disease and 95 tested negative, what is the diagnostic specificity of the test?
14. What parameter would be used to determine the percentage of patients who are appropriately classified as having a disease or not having a disease?
15. Which of the following statements describes the organization's purpose and what it does?
 - a. Vision statement
 - b. Mission statement
 - c. Values
 - d. Customer concept

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Identify the role of specimen management in the preanalytic laboratory process.
2. Outline the fundamentals of specimen collection.
3. State the goal of specimen preservation, storage, and transport to the laboratory.

4. Determine when preservatives and anticoagulants are used.
5. Justify the appropriate conditions for storage of specific specimen examples, such as urine and fecal samples.
6. Defend the prioritization guidelines used during processing to prevent degradation of the specimen.
7. Analyze situations in which specimens are unacceptable, and summarize the action to be taken.
8. List the characteristics that can be noted from a macroscopic observation of the specimen.
9. Summarize the purposes of a direct microscopic examination, and identify specimen sources for which this technique is utilized and specimens for which the technique is not beneficial and not performed.
10. Compare the categories of media used in clinical microbiology, and explain how media are selected.
11. Determine the appropriate isolation technique to be used for each specimen source when inoculating solid media.
12. Specify the appropriate temperature and atmospheric conditions for incubation of routine specimens and to recover fastidious bacteria.
13. Summarize the steps involved in the culture workup and interpretation.
14. Devise a plan for processing nonroutine specimens.
15. Assess the significance of the communication of microbiology findings and the role of the laboratory in the postanalytic process.

KEY TERMS

Aerobe	Enrichment broth
Anaerobic transport system	Etiologic agent
Broth media	Expectorated sputum
Capnophile	Homogenization
Cary-Blair transport medium	Induced sputum
Clean-catch midstream urine specimen	Isolation streak
Differential media	JEMBEC system
Direct microscopic examination	Macroscopic observation
Enriched media	Microaerophile
	Nonselective media

Obligate anaerobe
Quantitative isolation
Selective media

Sodium polyanethol sulfonate (SPS)
Suboptimal specimen
Transport media

Case in point

Specimens collected in the pulmonary medicine department were delivered to the microbiology laboratory. In the specimen receipt area, it was noted that one of the bronchoscopy specimens had a loose lid, and a portion of the contents were spilled into the bag. The specimen was submitted in a double bag, and the outer bag appeared dry.

Issues to consider

After reading the technologist's case history, consider:

- The role of the laboratory in assessing the acceptability of specimens received
- The consequences of processing inadequate or improperly collected and transported specimens
- The steps that must be taken in rejection of specimens

A major goal of the microbiology laboratory is to aid in the diagnosis of infectious diseases. Appropriate specimen selection, collection, and transportation are critical if laboratory results are used to provide information that establishes a diagnosis and successful treatment. The microbiology laboratory scientist does not usually perform this preanalytic portion of the laboratory testing process, and yet it directly affects the test results. The data generated by the laboratory are influenced by the quality of the specimen and its condition when received. A poor specimen may result in failure to detect the infectious agent responsible for the patient's condition. It also may result in the administration of inappropriate therapy if treatment is given for a contaminant organism. Thus it is the responsibility of the laboratory scientist to ensure that appropriate specimen management is performed. The laboratory should establish procedures for specimen management, and these procedures must be distributed to all users and clients of microbiology laboratory services. A well-written handbook should be available at every patient care unit and should specify the policies for specimen collection and transport as well as test ordering. Training and education, such as in-service classes taught by the laboratory scientist, should be provided to the individuals collecting the specimens. The laboratory scientist must recognize and reject suboptimal specimens and educate other members of the medical team. Open communication between the laboratory scientist and other members of the medical support team is necessary for quality patient care. This chapter introduces the concepts of specimen collection and processing. The steps for ensuring specimen quality are discussed, along with the procedures to follow when suboptimal specimens are received. This chapter addresses the steps that follow specimen receipt and are involved in completing the processing for microbiology workup.

Basic principles of specimen collection

The laboratory can make accurate and useful determinations only if the correct specimen has been collected properly. The specimens to be analyzed are likely to contain living

organisms; the goal of the specimen collector is to maintain the viability of these organisms with minimal contamination.

Fundamentals

The following basic principles of specimen collection are fundamental to ensuring appropriate specimen management:

- If possible, collect the specimen in the acute phase of the infection and before antimicrobial agents are administered.
- Select the correct anatomic site for collection of the specimen.
- Collect the specimen using the proper technique and supplies with minimal contamination from normal biota (flora).
- Collect the appropriate quantity of specimen.
- Package the specimen in a container or transport medium designed to maintain the viability of the organisms and avoid hazards that result from leakage.
- Label the specimen accurately with the specific anatomic site and the patient information—patient's name and a unique identification number, as well as the date and time of collection.
- Transport the specimen to the laboratory promptly, or make provisions to store the specimen in an environment that will not degrade the suspected organism(s).
- Notify the laboratory in advance if unusual pathogens or agents of bioterrorism are suspected.

Collection procedures

Specimens for microbiology cultures should be collected in sterile containers except for stool specimens, which can be collected in clean, leakproof containers. Generally, swabs are not recommended for collection because they do not provide sufficient quantity, are easily contaminated, and can become dried out, leading to a loss of organisms. Swabs are appropriate for specimens from the upper respiratory tract, external ear, eye, and genital tract. The tips of swabs may contain Dacron, rayon, or calcium alginate. Cotton-tipped swabs tend to have excessive fatty acids that may be toxic to certain bacteria and are not recommended. Dacron or rayon polyester swabs have a wide range of uses. Swab collection systems are available that provide **transport media** and protect the specimen from drying.

Lesions, wounds, and abscesses present many problems to the microbiology laboratory. A wound is not an appropriate specimen source when the exact anatomic site is not provided. Before the specimen is collected, the area should be cleansed to eliminate as much of the commensal biota as possible. The specimen should be collected by needle aspiration whenever possible, rather than by swab from the advancing margin of the lesion. Aspirated material should be placed into a sterile tube or vial with transport media and not "squirted" onto a swab. [Table 6.1](#) lists specimen collection procedures.

Patient-collected specimens

In certain situations, patients are asked to collect the specimen themselves. Medical personnel should provide patients with thorough instructions on how to collect the sample and should not assume that the patient knows how to collect a particular type of specimen. Printed instructions in multiple

Table 6.1 Specimen collection guidelines

Specimen	Patient preparation	Container/Minimum quantity
Blood culture	Disinfect skin with alcohol and iodine or chlorhexidine before venipuncture	Blood culture media set (aerobic and anaerobic bottles) or Vacutainer tube with SPS, adults 20 mL per set, children 5–10 mL per set
Body fluids (abdominal, amniotic, ascites, bile, joint, pericardial, pleural)	Disinfect skin before needle aspiration	Sterile, screw-cap tube or anaerobic transport system, ≥ 1 mL
Catheter tips, IV (Foley catheters not cultured)	Disinfect skin before removal of catheter	Sterile, screw-cap container
Cerebrospinal fluid	Disinfect skin before aspiration	Sterile, screw-cap tube, bacteria ≥ 1 mL, fungi ≥ 2 mL, AFB ≥ 2 mL, virus ≥ 1 mL
Ear		
Inner	Clean ear canal with mild soap, aspirate fluid with needle if eardrum intact; use swab if eardrum is ruptured	Sterile, screw-cap tube or anaerobic transport system
Outer	Remove debris or crust from ear canal with saline-moistened swab; rotate swab in outer canal	Swab transport system
Eye		
Conjunctiva	Sample both eyes; use separate swabs moistened with sterile saline	Swab transport system
Corneal scrapings	Instill local anesthetic, scrape with sterile spatula and inoculate directly to agar	Agar available at bedside
Feces	Collect directly into container, avoid contamination with urine	Clean, leakproof container or enteric transport system
Fungal scrapings	Wipe nails or skin with alcohol	Clean, screw-cap container
Hair/nails/skin	Hair: 10–12 hairs with shaft intact Nails: Clip affected area Skin: Scrape skin at outer edge of lesion	
Genitalia		
Cervix/vagina	Remove mucus before collection; do not use lubricant on speculum; swab endocervical canal or vaginal mucosa	Swab transport system or JEMBEC transport system, Assay specific system if NAAT performed
Urethra	Flexible swab inserted 2–4 cm into urethra for 2–3 seconds or collect discharge	Swab transport system or JEMBEC transport system, Assay specific system if NAAT performed
Lesion/wound/abscess	Wipe area with sterile saline or alcohol	
Superficial	Swab along outer edge	Swab transport system
Deep	Aspirate with needle and syringe	Anaerobic transport system
Respiratory tract: lower		
Sputum	Rinse mouth or gargle with water, instruct to cough deeply into container	Sterile, screw-cap container
Bronchial specimens	Materials collected during bronchoscopy	Sterile, screw-cap container
Respiratory tract: upper		
Nasal	Insert premoistened swab with sterile saline 1 inch into nares	Swab transport system
Nasopharynx	Insert flexible swab through nose into posterior nasopharynx, rotate for 5 seconds	Swab transport system or direct inoculation to media
Throat	Swab posterior pharynx, tonsils, and inflamed areas	Swab transport system
Tissue	Disinfect skin; do not allow tissue to dry out; if necessary, moisten with sterile saline	Anaerobic transport system or sterile screw-cap container
Urine		
Clean-catch midstream	Cleanse external genitalia; begin voiding; after several mL have passed, collect midstream without stopping flow of urine	Sterile, screw-cap container or urine transport kit, 2–3 mL

Continued

Table 6.1 Specimen collection guidelines—cont'd

Specimen	Patient preparation	Container/Minimum quantity
Catheter	Cleanse urethral area, insert catheter, and allow first 15 mL to pass; collect remainder	Sterile, screw-cap container or urine transport kit
Indwelling catheter	Disinfect catheter collection port, aspirate 5–10 mL with needle and syringe	Sterile, screw-cap container or urine transport kit
Suprapubic aspirate	Disinfect skin, aspirate with needle and syringe through abdominal wall into full bladder	Sterile, screw-cap container or anaerobic transport system

AFB, Acid-fast bacilli; IV, intravenous; JEMBEC, agar plates for transporting cultures of gonococci; NAAT, nucleic acid amplification test; SPS, sodium polyanethol sulfonate.

languages attached to a collection device, combined with verbal instructions, is the most effective method. It may be necessary to read the instructions to the patient. The instructions should be written in simple language and pictures included to help the patient understand the procedure as it is verbally explained. The specimens commonly obtained by the patient are urine, sputum, and stool.

Urine

Instructions for urine collection must include an explanation of what a **clean-catch midstream urine specimen** means. A first morning specimen is preferred because it provides a more concentrated sample. The patient collects this specimen following cleansing of the external genitalia to reduce the presence of indigenous biota. Patients are asked to void without collecting the first portion of the urine flow and instead to collect the middle portion. The first portion of the urine flow washes contaminants from the urethra, and the midstream portion is more representative of the urine in the bladder. Personnel who collect catheterized specimens should also use this technique to eliminate organisms carried up the urethra during catheterization.

Sputum

Sputum specimens are often collected for the diagnosis of bacterial pneumonia. Lower respiratory tract specimens are among the most difficult specimens to collect adequately because they are contaminated with oropharyngeal biota. For this reason, they are one of the least clinically relevant specimens received for culture. Other specimens, such as blood or a bronchoalveolar lavage (BAL), may be more accurate in detecting the **etiologic agent** (i.e., the microorganism causing the disease).

Collection of a quality sputum sample requires thorough patient education and medical personnel oversight of the process. The first early morning specimen is preferred. The patient must understand the difference among sputum, saliva, and nasal secretions. Patients should rinse their mouth with water and expectorate with the aid of a deep cough directly into a sterile container (**expectorated sputum**). Patients with dentures should remove the dentures first. A single specimen should be adequate for detection of a bacterial lower respiratory tract infection. If fungal or mycobacterial infections are suspected, three separate early morning specimens are appropriate.

Respiratory therapy technicians may assist patients who are unable to expectorate a respiratory specimen. These

specimens may be collected through aerosol induction in which the patient breathes aerosolized droplets of a solution that stimulates cough reflex (**induced sputum**). When sputum specimens are submitted to microbiology, the laboratory should be informed of whether the specimen was expectorated or induced.

Stool

The specimen of choice for the detection of gastrointestinal pathogens is stool. A rectal swab can be submitted for bacterial culture as long as fecal material is visible on the swab. A negative culture result for bacterial pathogens may require the submission of a second specimen. If a parasitic infection is suspected, three specimens collected within 10 days should be sufficient for microscopic detection of ova and parasites. Some laboratories offer an initial parasite screening for *Giardia lamblia* and *Cryptosporidium* spp. Newer methods detect parasite antigens, and one sample is usually sufficient. If the screen is negative, the physician can decide whether to perform complete parasite studies.

Patients should be instructed to defecate directly into the collection device. Specimens should never be taken from the toilet and should not be contaminated with urine. Commercial systems are available with preservatives for bacteria and parasites. The appropriate ratio of stool to preservative is 1:3, and the patient must understand that if this ratio is not met, the test will be invalid. Commercial transport containers are labeled with fill lines to aid in achieving the appropriate ratio. In addition, the patient needs to be told that the specimen must be thoroughly mixed with the preservative. Specimens for parasite microscopic studies should be collected before any barium studies are done. If this is not feasible, the patient must delay specimen collection until the barium has cleared (4 to 5 days). Barium appears as a white chalky substance in the specimen and masks the appearance of parasites under the microscope.

Culture-independent methods are becoming more available in laboratories. These molecular assays are highly sensitive and do not require multiple specimens. The collection container and transport will be specified by the assay manufacturer. Patients must be provided the instructions and collection devices.

Labeling and requisitions

It is important that correct patient identification be put on the specimen container and the requisition. The specimen label must contain sufficient information for the specimen and

requisition to be matched when received in the laboratory. The laboratory loses valuable time when specimens are unlabeled or mislabeled. Resolution requires making phone calls and filling out additional paperwork, and it ultimately delays processing the specimen or requires that a new specimen be collected. This may ultimately delay the diagnosis.

Proper identification of each specimen includes a label firmly attached to the container with the following information:

- Full patient name
- Date of birth
- Identification number
- Room number or location
- Physician
- Culture site
- Date and time of collection
- Name or initials of collector

To perform quality laboratory analysis, the laboratory needs specific information regarding the patient and the specimen. All that the laboratory knows about the patient is learned from the requisition form. The less information that is provided, the more difficult it is for the laboratory to provide good patient care. Incomplete information on the requisition form is often a weak link in the specimen management process. The requisition form should provide the following information:

- Patient's name
- Patient's age (or date of birth) and gender
- Patient's room number or location
- Physician's name, address, and phone number
- Specific anatomic site
- Date and time of specimen collection
- Clinical diagnosis or relevant patient history
- Antimicrobial agents (if patient is receiving any)
- Name of individual transcribing orders

Complete and thorough requisitions can often lead the laboratory scientist to suspect certain pathogens based on the diagnosis or patient history. This knowledge can allow use of specific media or making certain adjustments to the incubation to maximize recovery of the pathogen.

Computer-based ordering is performed at many institutions. Ideally, the laboratory scientist should design the test-ordering process; this will enable the laboratory to collect the necessary information. These systems should be designed to provide key fields that must be completed to submit the request transaction.

The laboratory scientist should recognize that the individual ordering the test does not have complete knowledge of what are and are not appropriate tests for each specimen. If the test requested is not recommended, it is the responsibility of the laboratory to communicate with the physician to determine exactly what must be done.

Safety

It is imperative that specimens collected for microbiology not pose a safety hazard to the individuals who handle them. Leaking containers and specimens with needles attached

present the greatest hazards. All specimens must be transported in leakproof secondary containers. Because the specimen should be kept separate from any paperwork, plastic bags with permanent seals and separate pouches on the outside for requisitions are recommended.

Transporting personnel should refuse to transport specimens without the protection of a secondary container. Refusing to accept syringes with needles attached is also appropriate. A needle must be replaced with a tight-fitting rubber stopper or a stopcock to put resistance on the plunger. The aspirated material could also be transferred to a sterile container with a tight lid or to an **anaerobic transport system**.

Laboratory personnel must also adhere to strict safety guidelines as they begin to work with the patient's specimen. All individuals handling patient specimens must wear protective clothing, and specimens should be opened only in a biosafety cabinet.

Case check 6.1

The laboratory can make accurate and useful determinations only if a specimen has been collected and transported properly. The goal of the specimen collector must be to maintain the viability of the living organisms and avoid hazards that result from leakage. The Case in Point clearly shows the laboratory's role in assessing the acceptability of the specimens it receives.

Preservation, storage, and transport of specimens

Specimen transport is another essential component of the preanalytic process of microbiology testing. Whether the specimen comes from within the hospital or clinic or from an outpatient facility or physician's office across town, the goal is the same. The primary goal in the transportation of specimens to the laboratory is to maintain the specimen as near to its original state as possible with minimal deterioration and to prevent risk to the specimen handler. If specimen deterioration results in death of the causative agent present or overgrowth of contaminants, the specimen is no longer representative of the disease process.

Specimens should be transported to the laboratory ideally within 30 minutes of collection, preferably within 2 hours. Adverse environmental changes in oxygen, pH, and temperature can prevent the recovery of certain microorganisms and allow overgrowth of others. If transport to the laboratory is delayed or if the specimen will not be processed as it is received in the laboratory, the specimen can be maintained by storage under certain conditions or with the use of preservatives, anticoagulants, transport or holding medium, or culture medium.

Specimen storage

Some specimens that will not be transported or processed immediately can be maintained by being stored under certain conditions. The individual responsible for storing the specimen must be informed as to the best storage

Table 6.2 Specimen storage guidelines

Refrigerate	Room temperature
Catheter tips (IV)	Abscess, lesion, wound
CSF for viruses	Body fluids
Ear: outer	CSF for bacteria
Feces (unpreserved)	Ear: inner
Feces for <i>Clostridioides difficile</i> toxin (up to 3 days; >3 days store at -70°C)	Feces (preserved)
Sputum	Genital
Urine (unpreserved)	Nasal, nasopharynx, throat
	Tissue
	Urine (preserved)

CSF, Cerebrospinal fluid; IV, intravenous.

environment for each specimen type. Some specimens, such as urine, stool, sputum, bronchial secretions, swabs (not for anaerobes), foreign devices such as catheters, and viral specimens, can be maintained at refrigerator temperature (4°C) for 24 hours. Pathogens that are cold sensitive may be found in other specimens, and those specimens should be kept at room temperature if culture is to be performed. This includes samples that might contain anaerobic bacteria as well as most other sterile body fluids, genital specimens, and ear and eye swabs. Fecal specimens submitted in preservatives can be maintained at room temperature. If cerebrospinal fluid is not processed immediately, it can be stored in a 35°C incubator for 6 hours. Table 6.2 lists specimen storage guidelines.

Preservatives

Two specimen types in which preservatives can be used are urine and stool. Boric acid is used in commercial products to maintain accurate urine colony counts. The systems are designed to maintain the bacterial population in the urine at room temperature for 24 hours and are useful for collection of urine specimens at distant locations. Stool specimens for bacterial culture that are not transported immediately to the laboratory can be refrigerated; if the delay is longer than 2 hours, the specimen can be added to **Cary-Blair transport medium**. Stools for *Clostridioides difficile* toxin assay should be collected without a preservative and can be refrigerated. If the delay is expected to be longer than 48 hours, the specimen should be frozen at -70°C . Preservatives for ova and parasite (O & P) examinations maintain the morphology of trophozoites and cysts. Laboratories often use a two-vial system in which one vial contains formalin for concentration and the other vial contains a fixative for preparing stained slides, such as modified polyvinyl alcohol with zinc.

Anticoagulants

Anticoagulants are used to prevent clotting of specimens, including blood, bone marrow, and synovial fluid. Organisms trapped in clotted material are difficult to isolate. The type of anticoagulant used and the concentration are important because some anticoagulants have antimicrobial properties. **Sodium polyanethol sulfonate (SPS)** is the most common anticoagulant used for microbiology specimens. The concentration of SPS must not exceed 0.025% (weight/volume) because some *Neisseria* spp. and certain anaerobes are

inhibited by higher concentrations. The ratio of specimen to SPS is important; different sizes of tubes must be available to accommodate adult and pediatric blood specimens and bone marrow or synovial fluid. Heparin is another acceptable anticoagulant and is often used for viral cultures and for isolation of *Mycobacterium* spp. from blood. Citrate and ethylenediamine tetraacetic acid (EDTA) should not be used for microbiology specimens.

Holding or transport media

Another way to maintain the integrity of the specimen from the time of specimen collection until laboratory processing of the sample is with the use of holding or transport media. These media usually contain substances that do not promote multiplication of microorganisms but ensure their preservation and are available in swab collection systems. Stuart or Amie transport medium is commonly used. Some transport systems contain charcoal to neutralize substances that can be detrimental to the survival of *Neisseria gonorrhoeae* and *Bordetella pertussis*. Flocked swabs (FLOQSwabs; Copan Diagnostics, Murrieta, CA) are also available that utilize materials to improve absorption and release of materials. These have been shown to be superior to wrapped swabs for pathogen recovery.

In certain situations, direct inoculation to culture media at the time of specimen collection (bedside inoculation) is optimal for isolation of the pathogen. Blood is usually placed into a broth culture medium immediately after collection. Synovial and peritoneal fluids also can be inoculated into blood culture broth bottles at the bedside. Besides the blood culture bottles, an additional specimen should be sent to the laboratory in a container for Gram stain. Specimens for *N. gonorrhoeae* can be placed directly onto a commercial transport system such as the **JEMBEC system** (John E. Martin Biologic Environmental Chamber; Thermo Fisher Scientific, Waltham, MA). This system contains selective agar and a carbon dioxide (CO_2)-generating tablet. Nasopharyngeal swabs for the isolation of *B. pertussis* also can be inoculated directly onto selective agar as they are collected. Specimens collected from the eye, especially cornea scrapings, also are inoculated directly to appropriate media as they are collected.

Specimens collected at the bedside are more susceptible to contamination. Any time culture medium is taken outside the laboratory, there is a possibility that it can become contaminated. The individual collecting the specimen must be informed regarding the appropriate way to manipulate the medium. In some situations, the laboratory scientist is asked to assist in the collection and can monitor the appropriate application of the specimen to the culture media. In other situations, media are maintained at the outpatient facility, and the culture is sent to the laboratory already inoculated with the specimen. It is the responsibility of the microbiology laboratory to ensure that the culture medium is of good quality when it is received to isolate the pathogens involved in the infection.

Shipping infectious substances

The shipment of clinical specimens and cultures of microorganisms is governed by a complex set of national and international guidelines issued by the U.S. Department of Transportation (DOT) and the U.S. Postal Service. International air shipment is regulated by the International

Civil Aviation Organization. The U.S. Congress requires the Secretary of Transportation to prescribe regulations for the safe transportation of hazardous material in commerce to ensure public safety and minimize risks in transportation. The regulations specify the way potentially infectious substances must be packaged to prevent leaks or spills and withstand pressure changes as well as how packages must be labeled to caution handlers and other parties about their hazardous content. The goal is to safeguard employees in the transportation industry and the general public. The duty of the laboratory is to use the appropriate packaging for each material being shipped and to label the package properly. Laboratories can purchase packaging materials specifically designed for transporting laboratory specimens.

Infectious substances are considered a hazardous material and must meet the requirements of the DOT Hazardous Material Regulations as published in the *Federal Register* Title 49 Code of Federal Regulations Parts 171 to 180 before being transported by rail, water, air, or highway. The DOT defines an *infectious substance* as a material known or suspected to contain a pathogen (bacteria, viruses, rickettsiae, parasites, fungi, or prions) that causes disease in humans or animals. Infectious substances are classified using a two-tier system: category A and category B. Category A substances are capable of causing permanent disability or life-threatening or fatal disease in otherwise healthy humans or animals upon exposure. Category B substances are not in a form generally capable of causing permanent disability or life-threatening or fatal disease in otherwise healthy humans or animals on exposure. Exposure occurs when the infectious substance is released

outside the protective packaging and results in physical contact with humans or animals.

Patient specimens or culture isolates must be triple-packaged before being shipped. The material is placed into a primary receptacle that must be watertight. Absorbent material is placed around the primary receptacle, and it is then placed into a secondary container that is also watertight. The secondary package is sealed and placed into a sturdy outer container constructed of fiberboard. Specific instructions must be followed for labeling the container as "Hazardous Material." Specimens that are shipped by air require specific labeling and shipping documents. Fig. 6.1 demonstrates the packaging of infectious materials for shipping.

Every employee who packages specimens and infectious materials for shipment must be appropriately trained. Training must include the DOT and International Air Transportation Association regulations; retraining should occur every 2 years if shipping by air or every 3 years if shipping by ground only, unless there are significant changes in the regulations.

Case check 6.2

The primary goal of specimen transport is to maintain the specimen as near to its original state as possible with minimal deterioration while protecting those handling the specimen. The Case in Point demonstrates the need for tightly sealed leakproof containers. Specimens should not be externally contaminated. Specimens that are grossly contaminated or compromised may be rejected.

Fig. 6.1 Packaging infectious substances for shipping: Category A Shipping. (From U.S. Department of Transportation, Pipeline and Hazardous Materials Safety Administration. (2019, December 4). *Transporting infectious goods safely*. CDC IPP Webcast. Available at: https://www.cdc.gov/cpr/ipp/webcast-2019/docs/DOT-Transporting-Infectious-Goods-Safely_508.pdf.)

Specimen receipt and processing

Specimen priority

Specimens require prompt processing after arrival in the laboratory. Processing every specimen as soon as it is received is often impossible. Laboratory staffing and specimen load may have a significant effect on timely processing. Appropriate specimen management should include guidelines for prioritizing the handling of specimens. A four-level scheme of prioritization may be used based on the critical nature of the specimen or potential for specimen degradation. Table 6.3 lists clinical samples and the ways each can be prioritized in a four-level system.

Level 1 specimens are classified as critical because they represent a potentially life-threatening illness and are from an invasive source. They require immediate processing. Level 2 specimens are unprotected and may quickly degrade or have overgrowth of contaminating biota. The laboratory scientist must quickly provide an optimal growth environment for the fastidious organisms that may be found in these specimens. Level 3 specimens require quantitation. Delay in processing level 3 specimens may adversely affect the accuracy of quantitation.

If processing of level 2 and level 3 specimens is postponed, appropriate storage or preservation must be initiated. For example, urine and sputum specimens can be refrigerated. A refrigerator at the site of specimen processing is convenient for the laboratory scientist and makes it more likely that urine specimens will be refrigerated during peak workload times. Level 4 specimens are specimens that arrive in the laboratory in holding or transport

media. Processing of level 4 specimens may be delayed to process specimens of a more critical nature first.

In general, batch processing is not used for most specimens in microbiology; however, in a few situations, it is appropriate. Specimens for acid-fast bacilli that need to be digested and decontaminated can be refrigerated and processed once per day. Stool specimens for O & P examinations that are in preservative also can be processed in batch format. Specimens for viral culture that are collected in viral transport media also can be batched.

Unacceptable specimens and specimen rejection

The analytic phase of the laboratory testing process begins as the specimen is received in the laboratory. On receipt in the laboratory, the specimen must be examined to ensure that it has been properly selected, collected, and transported. Performing tests on specimens that are of poor quality would yield misleading information that might result in misdiagnosis and inappropriate therapy. The microbiology laboratory must establish and publish the criteria for specimen rejection. The following situations are examples of **suboptimal specimens** that must be rejected:

- The information on the requisition does not match the information on the specimen label. If the patient name or source does not match, the specimen should be collected again.
- There is no patient identification on the specimen container.
- The specimen is not submitted in the appropriate transport container, or the container is leaking or grossly contaminated externally.
- The quantity of the specimen is inadequate to perform all tests requested.
- The specimen transport time is more than 2 hours, and the specimen has not been preserved.
- The specimen is received in a fixative such as formalin; stools for O & P examinations are an exception.
- An anaerobic culture is requested on a specimen in which anaerobes are indigenous.
- Microbiology processing of a particular specimen results in questionable data (e.g., Foley catheter tip).
- The specimen is dried up.
- More than one specimen from the same source was submitted from the same patient on the same day; blood cultures are an exception.
- One swab was submitted with multiple requests for various organisms.
- Gram stain of expectorated sputum reveals fewer than 25 white blood cells (WBCs) and more than 10 epithelial cells per low-power field and mixed bacterial biota.

All rejected specimens require a phone call to the person in charge of collecting the specimen. The laboratory should never discard an unacceptable specimen before contacting a member of the health care team. The laboratory must document the situation, indicating the reason for the rejection of the specimen. If the physician insists on processing an inadequate specimen, the laboratory report must include a comment explaining the potentially compromised results.

Table 6.3 Levels of specimen prioritization

Level	Description	Specimens
1	Critical/invasive	Amniotic fluid Blood Brain Cerebrospinal fluid Heart valves Pericardial fluid
2	Unpreserved	Body fluids (not listed for level 1) Bone Drainage from wounds Feces Sputum Tissue
3	Quantitation required	Catheter tip Urine Tissue for quantitation
4	Preserved	Feces in preservative Urine in preservative Swabs in holding medium (aerobic and anaerobic)

It may be necessary to process a suboptimal specimen in certain situations. Specimens that are impossible to recollect or that would require the patient to undergo another invasive procedure (bone marrow, spinal fluid, or surgery) may need to be processed regardless of the situation. The final report must include a notation indicating that the specimen was compromised.

Macroscopic observation

Processing patient specimens begins with a **macroscopic observation**. The gross appearance of the specimen may provide useful information to both the microbiologist and the physician. The physical characteristics of the specimen should be documented so that if different laboratory scientists work on the sample, they all will know the results of the gross examination.

Notations from the macroscopic observation should include the following:

- Swab or aspirate
- Stool consistency (formed, loose, or liquid)
- Blood or mucus present
- Volume of specimen
- Fluid—clear or cloudy

The gross examination also allows the processor to determine the adequacy of the specimen and the need for special processing. Areas of blood and mucus are selected for culture and direct microscopic examination. Anaerobic cultures may be indicated if gas, foul smell, or sulfur granules are present. The diagnosis is evident if adult helminths or tapeworm proglottids are present in the specimen.

Microscopic observation

A **direct microscopic examination** is a useful tool that provides rapid information. In critical situations, such as meningitis, the direct microscopic examination can be used to guide therapy choices when therapy must be initiated before culture results are available. Microscopic observation serves several purposes: (1) It can be used to determine the quality of the specimen. Sputum specimens that represent saliva rather than lower respiratory tract secretions can be determined by the quantitation of WBCs or epithelial cells. Similar assessment and determination can be made in samples collected from a wound site. Absence of WBCs may indicate that the sample may not have been taken from the actual site of infection. (2) It can give the laboratory scientist and the physician an indication of the infectious process involved. Gram stain of a sputum specimen revealing WBCs and gram-positive diplococci is indicative of *Streptococcus pneumoniae*. The routine culture workup can be guided by the results of the smear. The laboratory scientist can correlate the bacterial isolates with the types detected in the smear; this may alert the laboratory scientist to the presence of additional organisms not yet growing, such as anaerobes. It can dictate the need for nonroutine or additional testing. The presence of fungal elements in a specimen for bacterial culture would alert the laboratory scientist to notify the physician to request a fungal culture. Specimens may be received in many forms. Preparation of the direct smear depends on the type of material received. Techniques differ according to whether the specimen is a tissue, swab, or

fluid. See [Chapter 7](#) for a detailed explanation of the preparation and staining of smears.

In certain specimen types, the direct microscopic examination does not provide useful information and is not appropriate. Throat and nasopharyngeal specimens are examples. Gram stains for *N. gonorrhoeae* on specimens from the cervix and anal crypts are not recommended because these sites can contain other bacteria that can have the same morphology, although Gram stain direct smears are recommended to diagnose bacterial vaginosis. Gram stains on stool specimens are not usually routine, although they can be useful to determine whether the patient has an inflammatory diarrhea based on the presence of WBCs.

Although direct Gram stains on a urine specimen provide useful information, many laboratories do not perform them routinely because they are time-consuming, and preliminary culture results are available within 24 hours. Physicians can always request that a direct Gram stain be performed.

Primary inoculation

Types of culture media

Culture media may be divided into categories defined by the ability to support bacterial growth. **Nonselective media** support the growth of most nonfastidious microbes. Sheep blood agar is the standard nonselective medium used in the United States. **Selective media** support the growth of one type or group of microbes but not another. A selective medium may contain inhibitory substances such as antimicrobials, dyes, or alcohol. MacConkey agar is selective for enteric gram-negative bacilli, and Columbia agar with colistin and nalidixic acid (CNA) is selective for gram-positive organisms. **Differential media** allow grouping of microbes based on different characteristics demonstrated on the medium (see Chapter 8). Media may be differential and nonselective (e.g., sheep blood agar is nonselective but differentiates organisms on the basis of hemolysis). Media can be differential and selective (e.g., MacConkey agar inhibits gram-positive organisms and differentiates gram-negative bacilli on the basis of lactose fermentation).

Enriched media contain growth enhancers that are added to nonselective agar to allow fastidious organisms to flourish. Chocolate agar is an enriched medium. **Enrichment broth** is a liquid medium designed to encourage the growth of small numbers of a particular organism while suppressing other biota present. Enrichment broths are incubated for a certain period and then must be subcultured to isolate the particular organism. Lim broth (Todd Hewitt broth with CNA) is used to enhance the growth of group B streptococci. **Broth media** can be used as a supplement to agar plates to detect small numbers of most aerobes, anaerobes, and microaerophiles. Thioglycollate broth is an example of a supplemental broth media.

Culture media selection

The selection of media to inoculate is based on the type of specimen submitted for culture and the organisms likely to be involved in the infectious process. Specimens in which fastidious pathogens are more likely involved require media with appropriate nutrients to aid in their recovery. Specimens

that are collected from a site containing normal biota require types of media to diminish the normal biota, while allowing the pathogens to be detected.

Selection of primary culture media is standardized for routine bacterial cultures. However, individual laboratories may prefer one medium to another on the basis of past experience, patient population, or other circumstances. A table of media to be inoculated for each specimen should be available in the specimen processing area. See [Table 6.4](#) for primary culture media selection for specific body sites; equivalent media may be substituted. In some laboratories, the computer generates labels for media as the specimen is accessioned. Some specimens require a single plate, whereas others require a battery of several plates. If several plates will be inoculated, the labeled media should be arranged in order, beginning with the most enriched medium and progressing to the most selective. The specimen can be applied to each culture medium, and inhibitory substances will not be carried over from one agar to another.

The routine primary plating media include the following items:

- Nonselective agar plate.
- Enriched medium for fastidious organisms for normally sterile body fluids or a site in which fastidious organisms are expected.
- Selective and differential medium for enteric gram-negative bacilli for most routine bacterial cultures.
- Selective medium for gram-positive organisms for specimens in which mixed gram-positive and gram-negative bacteria are found.
- Additional selective media or enrichment broths for specific pathogens as needed.
- Broth medium may be used as a supplement with specimens from sterile body fluids (e.g., tissues, lesions, wounds, and abscesses).

Specimen preparation

Most specimens arrive in the laboratory in one of three forms: swab, tissue, or fluid. Specimens such as sterile body fluids, pus, urine, and sputum are inoculated directly onto selected media. Large volumes of sterile body fluids (peritoneal, pleural, continuous ambulatory peritoneal dialysis) are concentrated to increase the recovery of bacteria. Centrifugation and filtration are methods for concentration. If the volume of fluid is greater than 1 mL, the specimen can be centrifuged for 20 minutes at 3000g. The sediment is then used to inoculate media and to prepare smears. If the specimen consistency is thin enough to avoid filter clogging, filtration with a Nalgene filter unit can be performed. After filtration, the filter is removed and placed on the surface of an agar plate.

Specimens received on swabs can be inoculated directly to culture media. The specimen should be submitted on two swabs: one is used for the culture media, and the other is used to make the direct smear. Some laboratories place the swab into 0.5 to 1.0 mL of broth or saline and then vortex the specimen to loosen material from the swab and produce an even suspension of organisms. A sterile pipette is used to dispense the inoculum onto plates and broth. Tissues can be prepared for culture by **homogenization**, in which the tissue is ground

in a tissue grinder. Because homogenization can destroy certain organisms (i.e., fungal elements), in some situations the tissue is minced with sterile scissors and forceps into small pieces suitable for culture.

Isolation techniques

Specimens can be inoculated to agar plates by using a general-purpose **isolation streak** to yield a semiquantitative estimate of growth. The specimen is applied by rolling the swab or placing a drop of liquid specimen onto a small area at the edge of the plate. Broth media can be inoculated by placing a few drops of the liquid specimen into the tube of broth or placing the swab into the broth. The inoculating loop is sterilized and allowed to cool thoroughly before streaking the agar. The cooled loop is passed back and forth through the inoculum in the first quadrant several times. The first quadrant should be at least one quarter of the plate, and the streak lines should be close together. The plate is turned, and quadrant two is streaked by passing the loop through the edge of the first quadrant a few times and then streaking the rest of the area. The plate is turned again, and the loop is passed a few times through the edge of quadrant two and into the rest of the third quadrant. Finally, passing the loop over the final area of the agar streaks the fourth quadrant. It may be necessary to flame the loop or turn the loop over in between quadrants, depending on the number and type of bacteria present in the specimen. Laboratory personnel must adjust their technique as necessary. When more than one agar plate is used, the loop is flamed in between plates to prevent carryover of a possible contaminant from one plate to another. The use of gamma-sterilized disposable loops eliminates the step of flaming the loop between quadrants or between plates. [Fig. 6.2](#) illustrates this technique.

The general-purpose isolation streak is useful for most specimens. The relative number of organisms can be estimated based on the extent of growth beyond the original area of inoculum. Growth only in the first quadrant can be graded as 1+, or light growth; growth in the second or third quadrant can be graded as 2+ to 3+, or moderate growth; and growth in the third or fourth quadrant can be graded as 4+, or heavy growth. Some specimens require a quantitative technique to determine the number of bacteria present. Urine specimens are inoculated using **quantitative isolation**. Plates are inoculated using a calibrated loop to deliver a specified volume. The urine is mixed well, and the calibrated loop (0.01 or 0.001 mL) is vertically inserted into the urine and transferred to the culture medium by making a single streak down the center of the plate. Without flaming, the loop is streaked back and forth through the original inoculum. [Fig. 6.3](#) illustrates this technique.

Incubation

Once the medium is inoculated, incubation conditions must be considered. The incubation conditions include both temperature and environmental atmosphere and are determined by the type of specimen and the anticipated pathogens. The laboratory processing area should contain a chart or table stipulating where each medium should be placed for incubation. Most bacteria cultures are incubated

Fig. 6.3 Quantitative isolation technique.

at 35° to 37°C. Aerobes grow in ambient air, whereas **obligate anaerobes** cannot grow in the presence of oxygen and require an anaerobic atmosphere. Laboratories can achieve an anaerobic environment through the use of jars, bags, or a chamber. Some bacteria are **capnophiles** and require an increased concentration of CO₂; this can be achieved by a candle jar, a CO₂ incubator, jar, or bag. **Microaerophiles** grow with reduced oxygen and increased CO₂ and can be isolated using jars or bags. The length of incubation differs for individual organisms. Most routine bacterial cultures are held for 48 to 72 hours. Cultures for anaerobes and broth cultures may be held for 5 to 7 days. Unusual organisms may require special media or conditions beyond the routine. It

is helpful if the clinician indicates to the laboratory that an unusual organism is suspected. Table 6.5 lists unusual or fastidious organisms, recommended media, and incubation requirements.

Case check 6.3

Performing tests on specimens of poor quality would yield misleading information that could have a detrimental effect on patient care. The steps that must be taken to deal with the suboptimal specimen described in the Case in Point are as follows:

- Notify the physician to explain concerns about the specimen.
- Process the specimen because it cannot be recollected, utilizing appropriate safety measures.
- Include a disclaimer in the test report indicating the potential for compromised results.
- Document all steps/actions taken with the date, time, and who was notified.

Culture workup

The next part of the microbiology analysis is reading and interpreting the cultures. The laboratory scientist examines the culture medium and uses considerable skill and judgment in the interpretation. This interpretive judgment is the fundamental means of arriving at a result that is accurate and clinically relevant. The following questions are asked as each specimen is examined:

- What is the specimen source?
- Does this source have normal biota, or is it a sterile site?
- If normal biota is present, what bacteria are found, and what do these colonies look like?
- What are the most likely pathogens in this specimen?
- What is the colony morphology of these pathogens?
- Which medium is demonstrating growth, and what is the purpose of the medium?

This evaluation requires professional training to be able to recognize and distinguish normal biota from pathogens. The laboratory scientist must have knowledge of which organisms are pathogens in various body sites to perform a clinically relevant workup. The microscopic findings on the direct smear are incorporated into this decision-making process as they often provide a clue to the culture results.

Identification and antimicrobial susceptibility testing (when indicated) are performed on clinically relevant isolates. A challenging issue confronting laboratory scientists is the extent of the identification required. The laboratory scientist can ultimately save money by providing an accurate diagnosis in a timely fashion using a cost-effective strategy. Although definitive identification is the standard for quality patient care, microbiologists have incorporated limited identification procedures into their daily practice. These limited procedures help keep the laboratory testing cost-effective, while providing optimal patient care. Each laboratory must establish the protocol for the identification of various organisms. The introduction of newer technologies such as matrix-assisted laser desorption/ionization–time-of-flight

Table 6.5 Isolation of unusual or fastidious bacteria

Organism	Specimens	Media	Comments
<i>Bacillus anthracis</i>	Blood Skin lesion Sputum	Blood agar	Incubate at 35°–37° C, ambient air; hold plates for at least 3 days
<i>Bordetella pertussis</i>	Nasopharyngeal swab	Regan-Lowe or Bordet-Gengou agar	Bedside inoculation. Incubate at 35°–37° C, ambient air; hold plates for 6–7 days; DFA used in conjunction with culture
<i>Brucella</i> spp.	Blood Bone marrow	Commercial blood culture systems	Highly infectious by aerosol or penetration of unbroken skin; process all specimens in biosafety hood with protective equipment; incubate at 35°–37° C; most commercial systems detect growth in 7 days; conventional blood bottles should be held for 30 days and subcultured at 7, 14, and 30 days
<i>Corynebacterium diphtheriae</i>	Throat Nasopharyngeal Skin	Blood agar Loeffler agar slant Tinsdale or cystine-tellurite blood agar	Incubate at 35°–37° C, ambient air, toxigenicity testing necessary to confirm pathogenicity
<i>Francisella tularensis</i>	Eye Lymph node aspirate Skin ulcer Sputum Throat	Glucose cystine agar	Highly infectious by aerosol or penetration of unbroken skin; recommended that specimens be sent to laboratory equipped to handle them
<i>Haemophilus ducreyi</i>	Genital lesion Lymph node aspirate	Supplemented chocolate agar	Incubate at 33°–35° C, 3%–5% CO ₂ with high humidity; hold for 5 days
<i>Helicobacter pylori</i>	Gastric biopsy	BHI Brucella agar Supplemented Columbia agar	Incubate at 35°–37° C, microaerophilic atmosphere with high humidity; hold for 10 days, direct smear with silver or Giemsa stain may be diagnostic
<i>Legionella</i> spp.	Blood Lung Pleural fluid Sputum	BCYE α agar Selective BCYE α	Incubate at 35°–37° C, ambient air with high humidity; hold for at least 7 days, DFA available
<i>Nocardia</i> spp.	Brain Sputum Subcutaneous aspirate Tissue	Blood agar BHI agar SDA BCYE TM agar	Incubate at 35°–37° C, 3%–5% CO ₂ ; hold for 2–3 weeks
<i>Streptobacillus moniliformis</i>	Blood Lymph node Joint fluid	Serum-supplemented medium	Inhibited by SPS, citrate used as anticoagulant; incubate at 35°–37° C, 3%–5% CO ₂ ; hold for at least 7 days
<i>Vibrio</i> spp.	Blood Feces Lesion Tissue	Blood agar MacConkey agar TCBS agar Alkaline peptone water (enrichment for feces)	Selective agar (TCBS) needed only for fecal specimens; incubate at 35°–37° C, ambient air; hold for 3 days

BCYE, Buffered charcoal yeast extract; BCYE α , buffered charcoal yeast extract with 0.1% α -ketoglutaric acid; BHI, brain-heart infusion; DFA, direct fluorescent antibody; SDA, Sabouraud dextrose agar; SPS, sodium polyanethanol sulfonate; TCBS, thiosulfate-citrate-bile salts-sucrose; TM, Thayer-Martin.

mass spectrometry that enable definitive identification in a matter of minutes may change the approach that is taken in the workup of cultures.

Nonroutine specimens

Routine specimens have standardized processing procedures that are well established in the microbiology laboratory. However, the microbiology laboratory may be requested to process nonroutine specimens for which no processing procedures are established. In situations in which standardized procedures do not exist, the laboratory must use a standardized thought process to ensure that these specimens can be cultured in an appropriate fashion. This process begins by considering the following issues:

- Is the specimen likely to contain low numbers or high numbers of organisms? If there are low numbers of organisms, concentrating the specimen is advantageous. When few organisms are anticipated, large amounts of specimen yield better results.
- If the number of organisms is extremely low, is it important to enhance their number?
- Some specimens are being checked for sterility, and the presence of even one organism is significant. Use of a broth is important when growth must be enhanced.
- Are the organisms to be found in a specific specimen likely to be fastidious or nonfastidious? The choice of media, temperature, atmosphere, and length of incubation depends on whether the organisms are fastidious or nonfastidious.
- Is any normal biota associated with the specimen? The presence of normal biota might make special collection techniques important. It also dictates rapid transportation and timely processing.
- Does the specimen contain any preservatives or growth inhibitors that must be counteracted? Sometimes the effects of a preservative can be eliminated or reduced by dilution or use of a specific medium.
- What is a reasonable amount of specimen to culture? Are all areas of the specimen homogeneous, or will the portion chosen for culture affect the results? A 12-cm piece of vein received for culture may contain plaque on only a relatively small portion. Sampling one spot may not be representative of the whole. Sampling and grinding small pieces from multiple sites may be necessary.
- Is the objective to select a single agent from a mixed culture? An enriched or selective medium is helpful for this type of isolation.
- Is there a need to culture both external and internal surfaces? The surface to be cultured becomes important in devising beneficial methods of culturing catheters and other inanimate objects.

Nonroutine specimens may include vein grafts, multiple-lumen catheters, heart valves, implant soak solutions, perfusates, water samples, and equipment. The microbiology laboratory must establish the protocol and appropriate procedures for processing these samples. A description of the processing of some of these follows:

- *Implant soak solutions:* A large volume of soak solution and concentration is required because even one organism may be important. A broth with heavy inoculation, cytocentrifuge smear, and a large volume of filtered specimen placed on a chocolate agar plate should enable detection of low numbers of organisms.
- *Water sterility specimens:* Water from sources such as whirlpools, stills, and reagent water also requires concentration. The Millipore sampler (Millipore, Billerica, MA) is designed for this purpose and uses 18 mL of water.
- *Intrauterine devices (IUDs):* IUDs are usually cultured for the detection of *Actinomyces* spp. The device can be inoculated into a tube of thioglycollate broth.
- *Vascular catheter tips:* Vascular catheter tips are submitted for culture to aid in the diagnosis of catheter-related infection. The Maki roll technique is used in many laboratories. Using sterile forceps, a 5- to 7-cm segment of the catheter is rolled across the surface of a blood agar plate four times. After incubation, the laboratory performs identification and susceptibility tests on each organism that produces 15 or more colonies.

Case check 6.4

After cultures are incubated, the laboratory scientist evaluates the media to determine whether any potential pathogens are present. The laboratory scientist must distinguish normal biota from potential pathogens based on colony morphology. Identification of the isolate is done using stains and biochemical testing. Antimicrobial susceptibility testing will be performed on clinically relevant isolates. The culture results from the bronchoscopy specimen from the Case in Point will be evaluated and worked up according to laboratory protocol. A disclaimer will be included in the culture result indicating that the specimen was compromised during transit and the results must be interpreted with caution.

Communication of laboratory findings

The postanalytic phase of the laboratory testing process is the communication of laboratory findings. The laboratory scientist has a professional responsibility to the patient to communicate the laboratory results to the health care professional treating the patient. The laboratory must strive to provide accurate and timely information. In some situations, preliminary results are communicated as they become available. The physician can then take action on the results to provide effective patient care.

The report should clearly interpret the results and be free from microbiology jargon or abbreviations. The clinician may be unfamiliar with the laboratory procedures or the taxonomic status of the organisms involved, and it may be necessary to include interpretive statements to aid in the clinician's understanding.

Some microbiology results are considered critical values and must be reported to the physician immediately. Critical values may indicate a life-threatening situation that must be acted on promptly. The microbiology director, in consultation

BOX 6.1 Examples of critical values in microbiology

- Positive blood culture
- Positive cerebrospinal fluid Gram stain or culture
- Positive cryptococcal antigen test or culture
- Positive blood smear for malaria
- *Streptococcus pyogenes* from a sterile site
- Positive acid-fast smears or positive *Mycobacterium* culture
- *Streptococcus agalactiae* or herpes simplex virus from genital site of a pregnant woman at term
- Detection of significant pathogen (e.g., *Bordetella pertussis*, *Brucella* sp., *Legionella* sp.)

with the medical staff, should establish a list of these critical values. **Box 6.1** provides an example of critical values.

Additionally, the laboratory scientist is responsible for reporting certain infectious diseases to public health entities. It is essential that the microbiology department know which infectious agents are reportable and to which agency.

POINTS TO REMEMBER

- The microbiology laboratory must take responsibility for specimen management in the preanalytic laboratory process by ensuring that specimens are appropriately selected, collected, and transported.
- The collection of specimens for microbiology must include the use of proper technique and containers, adequate quantity, accurate labels, and prompt transportation or provisions to maintain specimen integrity.
- Shipping of clinical specimens or cultures of microorganisms must be performed according to the regulations of the DOT Hazardous Material Regulations.
- The microbiology laboratory must prioritize the processing of specimens as they are received in the laboratory based on the critical nature of the infection and the potential for specimen deterioration.
- Performing microbiology analysis on suboptimal specimens provides misleading results. The laboratory must publish guidelines for specimen rejection, and when a specimen is rejected, the laboratory must communicate this information to the person responsible for the patient.
- Macroscopic observation of the specimen allows the processor to determine the adequacy of the specimen and the need for special processing. A direct microscopic examination is useful in determining the quality of the specimen, detecting the etiologic agent, and alerting the laboratory scientist to use special procedures.
- The selection of culture media for each specimen is based on the anatomic site and the organisms likely to be involved in infection at that site. Specimens with fastidious pathogens require enriched media; specimens with an abundance of normal biota require selective media.
- If several plates are inoculated with a specimen, the media should be arranged in order, beginning with the most enriched medium and progressing to the most selective.
- The general-purpose isolation streak yields a semiquantitative estimate of growth, whereas the quantitative isolation technique will determine the number of bacteria present in a certain volume of the specimen.

- Most bacterial cultures are incubated at 35° to 37°C. The atmosphere will differ depending on the pathogens involved and may involve room air, CO₂, microaerophilic, or anaerobic conditions.
- Microbiology cultures are interpreted using skills to discriminate between normal biota and potential pathogens. The laboratory scientist must have knowledge of which organisms are pathogens in various body sites to perform a clinically relevant workup.
- The laboratory scientist performs definitive identification using accepted limited identification procedures to maintain cost-effective testing while providing optimal patient care.
- The microbiology laboratory contributes to effective patient management by communicating accurate and timely results.

LEARNING ASSESSMENT QUESTIONS

- Which one of the following involves specimen management in the preanalytic process?
 - Selecting the appropriate medium for culture
 - Performing a direct microscopic examination
 - Rejecting suboptimal specimens
 - Communicating the results of the specimen culture
- A patient has a subcutaneous infection, and the specimen is submitted on a swab. Explain why this is an unacceptable collection method. How should the sample be collected?
- Which of the following anticoagulants is appropriate for use in microbiology?
 - Citrate dextrose
 - EDTA
 - SPS
 - Sodium citrate
- Which of the following specimens should not be refrigerated?
 - Urine
 - Urogenital swab
 - Throat swab
 - Sputum
- Which of the following specimens requires immediate processing when received in the microbiology laboratory?
 - Urine
 - Cerebrospinal fluid
 - Sputum
 - Stool
- Which of the following is (are) reasons to reject a specimen for culture?
 - The specimen is preserved in formalin.
 - Information on the requisition does not match information on the specimen label.
 - A second stool sample is submitted from the same patient on the same day.
 - All of the above.
- Which one of the following is noted from a macroscopic observation?
 - White blood cells
 - Tapeworm proglottids
 - Epithelial cells
 - Protozoan cysts

8. In which of the following specimens is a direct microscopic examination not useful?
 - a. Throat swab
 - b. Sputum
 - c. Urine
 - d. Leg abscess
9. Chocolate agar is an example of which of the following?
 - a. Nonselective and differential media
 - b. Selective media
 - c. Differential media
 - d. Enriched media
10. Which of the following is an example of a selective and differential medium?
 - a. Blood agar
 - b. Chocolate agar
 - c. MacConkey agar
 - d. Modified Thayer-Martin agar
11. Which of the following specimens is cultured using a quantitative isolation technique?
 - a. Urine
 - b. Sputum
 - c. Blood
 - d. Stool
12. Cultures of *Bordetella pertussis* are incubated in ambient air at 35°C for 6 to 7 days. True or false?
13. Compose a list of questions that the laboratory scientist uses when doing a workup of a culture.
14. The microbiology laboratory receives a vascular catheter tip for culture. How should this specimen be processed?
15. What is the role of the microbiology laboratory in the postanalytic process?

material, and purulence, and differentiate them from microorganisms that may be present in the clinical sample.

3. Describe the morphology of the microorganisms present in a direct Gram-stained smear using the descriptive terminology presented.
4. Associate the following morphology with common species:
 - Gram-negative bacilli, small, pleomorphic
 - Gram-positive cocci in clusters or chains
 - Gram-positive diplococci
 - Gram-negative diplococci
 - Gram-positive filamentous branching rods
 - Yeasts and pseudohyphae
5. Associate the direct smear results with the organisms recovered from culture.
6. Apply quality control procedures used in the microbiology laboratory to the interpretation of the direct microscopic examination and resolve any discrepancies when present.

Monomicrobial

Polymicrobial

Probe-mediated stain

Purulence

Simple stain

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Given a list of stains commonly used in the medical microbiology laboratory, select the appropriate staining characteristic for determining whether a microbe is a bacterium or mycobacterium, fungus, or viral inclusion.
2. Given a photomicrograph of a Gram-stained direct smear of material from an infected site, describe the local material, contaminating

Case in point

A 75-year-old male patient with a history of chronic obstructive pulmonary disease, heavy smoking, and alcohol abuse came to his physician with a fever, chills, and a productive cough. Sputum samples were sent to the laboratory for direct smear and culture. Blood cultures also were drawn three times within 24 hours of hospital admission. The direct smear was

Gram-stained (Fig. 7.1). The sputum culture produced a heavy growth of α -hemolytic colonies. Blood cultures yielded similar results after 24 hours of incubation.

Issues to consider

After reading the patient's case history, consider:

- The role of the Gram stain and microscopic morphology in identification of microorganisms
- The presence of purulence (inflammation) in the direct smear of the specimen and its significance
- The evidence of contamination by normal (resident) microbiota (flora) and what it indicates
- The significance of the suspected organism observed—if it is “real” or an artifact
- The results for the microorganisms used as quality control (QC) to determine whether the Gram stain procedure was performed properly on the direct smear
- The stained appearance of the elements present (e.g., polymorphonuclear cells, red blood cells, and epithelial cells) to ensure that their appearance is correct

Differential staining and microscopy provide the foundation of the laboratory diagnosis of infectious diseases. Direct microscopy, visualization of microorganisms in clinical specimens, has been possible for more than 200 years. However, it was not a practical reality until Koch established the germ theory of disease in the 1880s. By 1880, a Scottish surgeon had published his direct observations of cluster-forming cocci in **purulence** from human disease. He named these cocci *Staphylococcus*. In 1884, Christian Gram developed the **Gram stain**, which places most bacteria into one of two groups: **gram-positive bacteria** or **gram-negative bacteria**. Since then, the Gram stain has allowed microbiologists to examine a clinical specimen directly for microorganisms such as the gram-positive coccus *Staphylococcus*. There are now several stains available to help microbiologists visualize microorganisms in clinical samples. Because of their small size, viruses cannot generally be detected by staining.

Fig. 7.1 Expecterated sputum smear, Gram stain, light microscopy (medium-power view). Purulence, light. Amorphous debris, moderate. Gram-positive diplococci, encapsulated, extracellular.

However, the morphologic changes some viruses cause in infected cells can be seen and might aid in the identification of a viral infection. These changes are called *cytopathic effect* (see Chapter 29).

In many instances, the physician has a correct idea about the diagnosis after taking a patient history and performing a physical examination. In other instances, in which the diagnosis is not evident, assistance comes from laboratory or radiologic studies. With infectious diseases, the physician might have an idea of the likely etiology from the rate of symptom progression and is able to evaluate the extent of the infectious process. Nevertheless, specimens are collected and sent to the laboratory to confirm the physician's suspicions about the patient's illness. Direct viewing of pathogens becomes primary or direct evidence to confirm or refute the physician's initial clinical impression. Hence, the ability of the laboratory to respond quickly to the physician with useful results is key to appropriate treatment or changing treatment if the physician's presumptive diagnosis was incorrect. The diagnostic microbiology laboratory has the opportunity to respond to the physician during the treatment decision-making process or early in presumptive therapy. If this impression is incorrect, reconsideration is facilitated, and additional studies can be undertaken as needed. Culture results usually are received too late to alter presumptive therapy. At best, they confirm the correctness of the therapeutic choices already made and implemented.

Preparation of samples

Samples for routine bright-field microscopy are prepared in a manner that facilitates adequate examination within a reasonable time. For smears, specimens should be examined grossly to determine the best approach (Table 7.1). Both thick, but not opaque, and thin (monolayer) smear areas should be produced by the smear process chosen.

Table 7.1 Preparing infected materials for visual examination

Preparation	Specimen or organism type
For gross examination	
Wet preparation	Parasites Materials >1 mm in size
For microscopic examination	
Wet preparation (direct or sedimented)	Fluids or semisolids
Cytoцентрифугед (direct or presedimented)	Clear or slightly turbid fluids
Smear	Clear or slightly turbid fluids
1. Drop	Pus Tissue homogenate
2. Pellet, centrifuged	Blood culture Dilute specimen
3. Rolled swab	Swabbed material
4. Imprint (touch preparation)	Tissue

Smears from swabs

Smears from swabs are prepared by rolling the swab back and forth over contiguous areas of the glass slide to deposit a thin layer of sample material (Fig. 7.2). This process preserves the morphology and relationships of the microorganisms and cellular elements. In addition, the swab should not be rubbed back and forth across the slide because important material on the opposite side of the swab might not be deposited, and cellular elements could be broken up. If the sample can be collected only on swabs, ideally two swabs are submitted. Smears should not be prepared from a swab after it has been used to inoculate culture media.

Smears from thick liquids or semisolids

Swabs also can be used for preparation of smears from thick liquid or semisolid specimens such as feces (Fig. 7.3). The swab is immersed in the specimen for several seconds and used to prepare a thin spread of material on the glass slide for staining and viewing. This swab method of preparation is adequate but may produce less desirable results than other methods.

Smears from thick, granular, or mucoid materials

Opaque material must be thinly spread so a monolayer of material is deposited in some areas. It is most desirable to have both thick and thin areas. Granules within the material must be crushed so their makeup can be assessed. A better

Fig. 7.2 Smear preparation of a sample collected on a swab. The swab should be rolled back and forth across the slide to deposit the sample completely.

Fig. 7.3 Smears from opaque thick liquids or semisolids, such as stool, can be made with a swab to sample and smear the material.

presentation of granules is possible if granules or grains are “fished” from the surrounding materials and crushed on a separate slide using the technique shown in Fig. 7.4. Granules that are too hard to crush between two glass slides probably do not represent infectious materials. More likely, they are small stones or foreign bodies. Examination using a dissecting microscope may help characterize the nature of hard granules.

Steps to prepare a smear from thick, granular, or mucoid materials are as follows:

1. Place a portion of the sample on the labeled slide, and press a second slide, with the label down, onto the sample to flatten or crush the components.
2. Rotate the two glass surfaces against each other so the shear forces break up the material.
3. Once the material has been flattened and sufficiently thinned, pull the glass slides smoothly away from each other to produce two smears.
4. If the material is still too thick, repeat the first three steps with another (third) glass slide. The best smear or both smears can be retained for staining.

Slides of material from difficult sample sites, scant samples, or patients with critical illnesses should not be discarded until the culture evaluation is complete.

Smears from thin fluids

Thin fluids such as urine, cerebrospinal fluid (CSF), and transudates can be prepared by drawing up a small quantity of the fluid or a resuspended sediment of the fluid into a pipette and depositing it as a drop of fluid onto a clearly marked area on the slide (Fig. 7.5). “Thin” specimens of fluids should not be spread on the slide. The area of sample drop should be marked on the reverse side of the slide using a wax pencil or placed within the circle or well of a premarked slide. If available, **cytocentrifugation** should be used to prepare this type of specimen. The material, after staining, may not be grossly visible because of a low protein or cell count.

Cytocentrifuge preparations

Cytocentrifugation is an excellent method for preparing non-viscous fluids such as CSF and bronchoalveolar lavage fluids. In the cytocentrifugation process, cellular elements and microorganisms from the specimen are deposited within a discrete area onto the surface of a glass slide as a monolayer for easy viewing (Fig. 7.6A). Protein, which stains gram-negative, is dissipated into a filter pad, leaving the background clearer for viewing gram-negative morphotypes. Cell morphology is good, and the concentrating effect shortens viewing time and increases the volume of cellular material reviewed.

Cytocentrifuge technique

A cytocentrifuge with a closed bowl is preferred for microbiology. The bowl can be loaded and unloaded within a biological safety cabinet to avoid possible infectious aerosols. The steps of the technique are as follows:

1. Small aliquots of fluid (0.1 to 0.2 mL) are placed in the cytocentrifuge holders.

Drop or place the sample onto the surface of a labeled glass slide.

Place the second slide face down over the material.

Press to flatten or crush the material, and rotate the two glass surfaces against each other.

Pull to spread.

Fig. 7.4 Preparation of smears from thick, granular, or mucoid samples.

Fig. 7.5 Smears from thin fluids can be prepared by placing a single drop of fluid or resuspended fluid sediment on a well-marked area of the slide.

A

B

Fig. 7.6 **A**, Cytocentrifuge preparations deposit the concentrated sample within a limited area for viewing. **B**, If the deposit is too heavy, a portion of the material may be smeared to produce a thin area.

2. The material is spun for 10 minutes.
3. The slide is removed. If the deposit of cells is too heavy, a portion of the cellular deposition can be smeared (see [Fig. 7.6B](#)).
4. The sediment is fixed and decontaminated in 70% alcohol for 5 minutes.

Stains

Staining imparts an artificial coloration to the smear materials that allows them to be seen using the magnification provided by a microscope. There are many types of stains: **simple stains**,

differential stains, and **probe-mediated stains**. Simple stains are directed toward coloring the forms and shapes present, differential stains are designed to color specific components of the elements present, and antibody or DNA probe-mediated stains are directed specifically at identification of an organism or virus. Some stains, such as India ink on spinal fluid, are used as wet mounts on liquid specimens. This is a differential stain allowing the detection of the encapsulated yeast *Cryptococcus neoformans*. Stains most commonly used in the diagnostic microbiology laboratory are listed in [Table 7.2](#). Four stains—Gram, **acid-fast**, calcofluor white, and rapid modified Wright-Giemsa—should be available in all diagnostic microbiology laboratories (see procedures in [Appendix D on Evolve](#)). Most other stains are directed toward specific organism groups and should be available when needed.

Microscopes

In most circumstances, the requested tests provide a guide to the examination of clinical specimens submitted for microbiologic studies. A routine approach to specimen management, however, should include an examination procedure that would discover unexpected pathogens. In most diagnostic

microbiology laboratories, this procedure consists of performing a gross visual inspection at the time of smear and culture preparation and then proceeding to the level of magnification needed to identify the pathogen or determine that no pathogen is present. The purpose of microscopic examination of a Gram-stained sample is to look for structures too small to be seen with the unaided eye.

Microscopes differ both in their ability to resolve small structures and in their modifications. Microscopes are divided into two basic types: compound light microscopes, with common resolving limits of 1 to 10 μm and enlargements up to $\times 1000$, and electron microscopes, with enlargements greater than $\times 1,000,000$ ([Table 7.3](#)). The microbiology laboratory uses several modifications of the compound light microscope, but the “workhorse” of the laboratory is the bright-field microscope.

Terminology for direct examinations

The microscopist must have a consistent vocabulary for the description of materials seen in samples. This vocabulary must be shared by the microbiology and medical communities so when observations are reported, everyone understands

Table 7.2 Stains for infected materials

Stains	Applications
General morphology	
Wright-Giemsa	Bronchoalveolar lavages Tzanck preparations Samples with complex cellular backgrounds (visualizes bacteria, yeasts, parasites, and viral inclusions)
Selected morphology	
Leifson	Flagella
Methylene blue	Metachromatic granules of <i>Corynebacterium diphtheriae</i>
Acid-fast stains	
Ziehl-Neelsen	Direct smears for mycobacteria in material from the lower respiratory tract Sediments for mycobacteria (concentrated smears) Partial acid-fastness of <i>Nocardia</i> spp.
Kinyoun	Direct smears for mycobacteria in material from the lower respiratory tract Sediments for mycobacteria (concentrated smears) Acid-fast stain modification of Ziehl-Neelsen method for <i>Cryptosporidium</i> and <i>Cyclospora</i> parasites in stool specimens
Fluorochrome	Direct smears for mycobacteria in material from the lower respiratory tract Sediments for mycobacteria (concentrated smear, auramine and rhodamine) Preferred acid-fast stain to detect acid-fast organisms
Calcofluor white	Bronchoalveolar fungi and some parasitic cysts Differentiates them from background materials of similar morphology
Gram stain	
Traditional	Routine stain for detecting microorganisms Yeasts differentiated from all other organisms
Enhanced	Provides same differential staining but enhances red-negative organisms by staining the background material green to gray-green
Genus (or species)-specific stains	
Antibody or DNA probe stains	Used for specific identification of selected pathogens, such as <i>Chlamydia trachomatis</i> , <i>Bordetella pertussis</i> , <i>Legionella pneumophila</i> , herpes simplex virus, varicella-zoster virus, cytomegalovirus, adenovirus, and respiratory viruses

Table 7.3 Observing microbial pathogens

Tools	Magnification (×)	Application
Unaided eyes	0	Gross examination
Magnifying glass	5	Gross examination
Dissecting microscope	2.5–30	Gross detailed examination and manipulation
Compound light microscope		
Bright-field	10–1000	Cells stained
Dark-field	10–400	Cells not readily stained for bright-field microscopy
Phase-contrast	10–400	Living or unstained cells
Fluorescence	10–400	Preparations using fluorochrome stains, which can directly stain cells or be conjugated to antibodies that attach to cells
Electron microscopes		
Transmission electron	150–2 million	Determine ultrastructure of cell organelles Visualize virus particles
Scanning electron	20–10,000	Determine cellular surface shapes and structures

the implications of the descriptions. Common observations can be coded so they are consistent among observers. The use of computers for recording coded observations and generating reports of the findings extends the need for uniform terminology further. Only unusual findings should be described individually in a report.

The background of the sample being evaluated should be described in sufficient detail to convey the composition of the material. The presence of cells representing a response to injury supports the probability of infection and directs attention toward specific types of pathogens. Common morphotype descriptions and the most prevalent associated species are listed in Table 7.4. Examples of useful descriptive phrases with quantitation are listed in Table 7.5.

Microorganisms can be described in such a way that, based on prevalence, the description implies the identification of the organism. For example, the observation of a gram-negative pleomorphic coccobacillus from the spinal fluid of a child implies that *Haemophilus influenzae* is the infecting agent.

Examination of prepared material

A limited number of microbial pathogens from commonly sampled infected sites are regularly encountered by the microbiologist. The Gram stain and acid-fast stain are the fastest and least expensive methods for presumptive diagnosis in common clinical settings. Organisms are readily seen

Table 7.4 Gram stain morphology and associated organisms

Morphotype description	Most common organisms
Bacteria	
Cocci	
Gram-positive cocci	<i>Aerococcus</i> , <i>Enterococcus</i> , <i>Finegoldia</i> , <i>Leuconostoc</i> , <i>Pediococcus</i> , <i>Planococcus</i> , <i>Staphylococcus</i> , <i>Stomatococcus</i> , <i>Streptococcus</i>
Gram-positive cocci	
Pairs	<i>Finegoldia</i> , <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Enterococcus</i> spp.
Tetrads	<i>Micrococcus</i> , <i>Staphylococcus</i> , <i>Peptostreptococcus</i> spp.
Groups	<i>Finegoldia</i> , <i>Staphylococcus</i> , <i>Peptostreptococcus</i> , <i>Stomatococcus</i> spp.
Chains	<i>Streptococcus</i> , <i>Peptostreptococcus</i> spp.
Clusters, intracellular	Microaerophilic <i>Streptococcus</i> spp., viridans streptococci, <i>Staphylococcus</i> spp.
Encapsulated	<i>Streptococcus pneumoniae</i> , <i>Streptococcus pyogenes</i> (rarely), <i>Stomatococcus mucilaginosus</i>
Gram-positive diplococci (lancet-shaped)	<i>Streptococcus pneumoniae</i> , often encapsulated
Gram-negative diplococci	<i>Pathogenic Neisseria</i> spp., <i>Moraxella catarrhalis</i>
Bacilli	
Gram-positive bacilli	
Small	<i>Listeria monocytogenes</i> , <i>Corynebacterium</i> spp.
Medium	<i>Lactobacillus</i> , anaerobic bacilli
Large	<i>Clostridium</i> , <i>Bacillus</i>
Diphtheroid	<i>Corynebacterium</i> , <i>Cutibacterium</i> , <i>Propionibacterium</i> , <i>Rothia</i> spp.
Pleomorphic, Gram-variable	<i>Gardnerella vaginalis</i>
Beaded	Mycobacteria, antimicrobial-affected lactobacilli, and corynebacteria

Table 7.4 Gram stain morphology and associated organisms—cont'd

Morphotype description	Most common prganisms
Filamentous	Anaerobic morphotypes, antimicrobial-affected cells
Filamentous, beaded, branched	<i>Actinomycetes</i> , <i>Nocardia</i> , <i>Nocardiosis</i> , <i>Streptomyces</i> , <i>Rothia</i>
Bifid or V forms	<i>Bifidobacterium</i> , <i>brevibacteria</i>
Gram-negative coccobacilli	<i>Bordetella</i> , <i>Haemophilus</i> (pleomorphic)
Masses	<i>Veillonella</i>
Chains	<i>Prevotella</i> , <i>Veillonella</i>
Gram-negative bacilli	
Small	<i>Haemophilus</i> , <i>Legionella</i> (thin with filaments), <i>Actinobacillus</i> , <i>Bordetella</i> , <i>Brucella</i> , <i>Francisella</i> , <i>Pasteurella</i> , <i>Capnocytophaga</i> , <i>Prevotella</i> , <i>Eikenella</i>
Bipolar	<i>Klebsiella pneumoniae</i> , <i>Pasteurella</i> , <i>Yersinia</i> , <i>Bacteroides</i>
Medium	Enterics, pseudomonads
Large	Devitalized clostridia or bacilli
Curved	<i>Vibrio</i> , <i>Campylobacter</i>
Spiral	<i>Campylobacter</i> , <i>Helicobacter</i> , <i>Gastrobacillum</i> , <i>Borrelia</i> , <i>Leptospira</i> , <i>Treponema</i>
Fusiform	<i>Fusobacterium nucleatum</i>
Filaments	<i>Fusobacterium necrophorum</i> (pleomorphic)
Yeasts and fungi	
Yeasts	
Small	<i>Histoplasma</i> , <i>Torulopsis</i>
Medium	<i>Candida</i>
With capsules	<i>Cryptococcus neoformans</i> and <i>Cryptococcus gatti</i>
Thick-walled, broad-based bud	<i>Blastomyces</i>
Hyphae	
Septate	Fungi
Aseptate (sparsely septate)	Zygomycetes
With arthroconidia	<i>Coccidioides</i>
With branches at a 45-degree angle	<i>Aspergillus</i>
Pseudohyphae	<i>Candida</i>
Spherule with endospores	<i>Coccidioides</i>
Sporangia with endospores	<i>Protothecae</i>

Table 7.5 Descriptions of background material

Cells and structures	Associations
Amorphous debris (light, moderate, or heavy)	Necrosis, heavy protein fluid
Black particulate debris	Smoke inhalation, crack cocaine
Charcot-Leyden crystals	Eosinophils
Curschmann's spirals (sputum)	Bronchospasm, obstruction, asthma
Epithelial cells (light, moderate, or heavy)	Epithelial surface involved or adjacent to collection site
Epithelial with contaminating bacteria	Passage of specimen through contaminated area during collection
Intracellular organisms	Inferred association in infection
Local material (light, moderate, or heavy)	Reflection of collection site
Mononuclear cells present	Chronic inflammation
Mucus (light, moderate, or heavy)	Irritation of glandular surface
Purulence (none, light, moderate, or heavy)	Acute inflammation, exudation
Red blood cells	Trauma, hemorrhage

because more than 10^5 **colony-forming units** of infecting organisms per milliliter are commonly present in clinically evident infections.

Two types of infection are important to distinguish: infections caused by a *single species*, or **monomicrobial**, and infections caused by *multiple species*, or **polymicrobial**. The single agents of infection or agents causing classic infections are easily recognized by microscopy and require limited interpretations. These agents and infections include *Streptococcus pneumoniae* pneumonia, *Staphylococcus aureus* abscesses or pyodermas, *H. influenzae* tracheobronchitis or meningitis in children, *Clostridium perfringens* gas gangrene, *Nocardia* spp. lung abscesses, and gonococcal urethritis in males (Fig. 7.7).

Polymicrobial presentations in smears require further interpretation and must consider the smear background, morphology of the organisms, and the anatomic location of the suspected infection as well as accompanying clinical symptoms. Polymicrobial infections usually arise from displaced normal or altered microbiota, and culture yields the same species that can be isolated in culture from uninfected but contaminated specimens. These infections usually represent displacement of environmental, skin, oropharyngeal, gastrointestinal, or vaginal biota into tissues, with subsequent infection. Commonly encountered infections of this type are surgical wound (skin biota) infection, aspiration (oropharyngeal biota) pneumonia, perirectal (fecal biota) abscesses, and tubo-ovarian (vaginal biota) abscess (Fig. 7.8).

Case check 7.1

The Gram-stained smear of the expectorated sputum sample taken from the patient described in the Case in Point (see Fig. 7.1) showed moderate, **amorphous debris** and extracellular, encapsulated, gram-positive diplococci. This is a typical smear presentation for early pneumococcal pneumonia. The pneumococci have proliferated to high numbers, and the lung is responding with increased mucus and fluid release. There is early migration of neutrophils, but phagocytosis of the diplococci is limited. Routine bacterial culture of this sample should yield a heavy growth of *S. pneumoniae*.

Fig. 7.7 Urethral exudate, smear, Gram stain light microscopy human papillomavirus (HPV). Purulence. Intracellular, gram-negative, diplococci consistent with *Neisseria gonorrhoeae* among numerous white blood cells known as *polymorphonuclear (PMN) leukocytes*. (Courtesy Bill Schwartz, Centers for Disease Control and Prevention, Public Health Image Library, Atlanta, GA.)

Characterization of background materials

The laboratory scientist should look at the slide material with the unaided eye before beginning the microscopic examination. The distribution and consistency of the material should be noted. The microscope's low-power objective ($\times 2.5$ to $\times 10$) should be used first to evaluate the general content of the material on the slide. Specimens can be homogeneous or heterogeneous and may contain pathogens evenly distributed throughout the specimen or limited to one visual field. A mental inquiry checklist should be followed until the habit of searching a slide systematically is developed. Items that should be included in such a checklist include:

- *Is there evidence of contamination by normal (resident) microbiota?* The laboratory scientist should look for squamous epithelial cells (SECs), bacteria without the cells of inflammation, food, or other debris. Does this material constitute the entire sample, or is there a representative sample also available in a manner that can be recognized? Contamination of specimens not collected from sterile sites diminishes the value of culture studies.
- *Is necrotic (amorphous) debris in the background?* Infection with organisms such as *C. perfringens* and *Nocardia* spp. may elicit few polymorphonuclear (PMN) leukocytes. The inflammatory cells that migrate into the area of infection can be lysed (Fig. 7.9). Patients with leukopenia also may have few inflammatory cells within their inflammatory debris. Amorphous debris usually is the remains of tissue mixed with the breakdown products or fluids of acute inflammation and always should be searched for organisms. *Mycobacterium tuberculosis* organisms stain poorly as beaded gram-positive bacilli or not at all with Gram stain (Fig. 7.10); they can appear within necrotic debris as negative images (Fig. 7.11).
- *Is there evidence of purulence?* Purulence with red blood cells, neutrophils, protein background, and necrosis reflects acute inflammation (Fig. 7.12). The image shows an abscess aspirate with the presence of heavy purulence. Mononuclear cells, including lymphocytes, monocytes,

Fig. 7.8 Aspirated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, light. Local materials, light. Gram-positive bacilli, large. Gram-negative bacilli, medium, intracellular. Gram-positive cocci, pairs, chains. Morphology suggests polymicrobial infection, aspiration pneumonia.

Fig. 7.9 Wound cellulitis, smear, Gram stain (medium-power view). Purulence, none. Amorphous debris, moderate. Gram-positive bacilli, large. Gram-negative bacilli, large. Morphology consistent with *Clostridium* spp. *Impression*: gas gangrene. The growth rate of this organism is rapid, and both viable (gram-positive, arrow 1) and nonviable (gram-negative) bacilli can be present in the smear material (arrows 2).

Fig. 7.10 Abscess aspirate, smear, Gram stain, light microscopy (high-power view). Purulence, moderate. Amorphous debris, light. Gram-positive bacilli, beaded (arrows). Suspect mycobacteria: initiate additional testing (see Plate 19).

Fig. 7.11 Expecterated sputum, smear, Gram stain, light microscopy (medium-power view). Amorphous debris, heavy. Bacillary shapes, negative image (arrows). Oil removed from smear, decolorized with acid alcohol, and immediately restained with Ziehl-Neelsen acid-fast stain. Acid-fast bacilli, numerous. Specimen recovered; acid-fast culture requested by laboratory. Suspicious for tuberculosis.

Fig. 7.12 Abscess aspirate, smear, Gram stain, light microscopy (medium-power view). Purulence, heavy. Gram-positive cocci, groups, extracellular. *Impression*: staphylococcal disease. Aerobic and anaerobic culture plates were negative at 24 hours. There was culture isolation of *Staphylococcus aureus* from this same abscess 5 days previously. The patient was being treated with clindamycin. Because the cocci in the smear did not appear to be damaged by the antimicrobial agent, another species of gram-positive coccus was sought. The anaerobic culture grew *Peptostreptococcus* sp., which is clindamycin resistant.

Fig. 7.13 Expecterated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, heavy. Local materials, Curschmann's spiral. No organisms seen. The Curschmann's spiral (arrow) is material local to the tracheobronchial tree but is not normal, so it is specifically reported. This spiral may manifest in various sizes depending on the size of the bronchus involved. Spirals can be particularly prominent after an asthmatic episode with bronchial constriction.

and macrophages, reflect chronic inflammation. Patients who are cytopenic do not have the cellular response seen in normal individuals. Purulence, blood, and necrosis can be present if traumatic tissue damage occurs in the absence of infection.

- *Are unexpected structures present?* The characteristic coiled structure of a **Curschmann's spiral** (Fig. 7.13), a mucus plug found in sputum of patients with asthma, is more easily recognized on low power. This structure must not be confused with parasitic larvae, which also can be found in sputum using low-power magnification. Large granules, grains, or fungal forms such as spherules or fungal mats can best be recognized at low power.

Search for microorganisms

After the full extent of the material has been examined on low power, a representative area should be selected for viewing with higher magnification. A $\times 40$ or $\times 60$ objective lens is preferred for scanning, and a $\times 100$ oil immersion lens is used for final evaluation. In infection, the organisms will be intimate with the purulence of necrotic debris. All grains or granules and the background should be examined carefully. The delicate gram-positive filaments of *Nocardia* spp. can blend into the background (Fig. 7.14). *H. influenzae* may be present in large numbers, hidden within the mucus, in acute exacerbations of chronic bronchitis (Fig. 7.15). Intracellular and extracellular forms should be noted. Strict criteria for **microbial morphotypes** should be maintained. The examiner must not be distracted by precipitated gram-positive stain, keratohyalin granules (Fig. 7.16) or other artifacts. Organisms should be evaluated for shape, size, and Gram stain reaction. Because cell wall-damaged bacteria, antimicrobial-treated bacteria,

Fig. 7.14 Expectorated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, heavy. Local materials, moderate. Grain present. Gram-positive bacilli, filamentous, beaded, branched (arrow). Suspicious for *Nocardia* or *Actinomyces* (see Plate 23).

Fig. 7.15 Expectorated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, moderate. Local materials, heavy. Mucus present. Gram-negative coccobacilli, intracellular, extracellular (arrows). Morphology consistent with *Haemophilus influenzae*.

or dead bacteria can appear falsely gram-negative, their shapes and sizes are critical “co-characteristics.” The classic misleading smear example is the observation of gram-negative, lancet-shaped diplococci mixed with the predominant gram-positive forms. An inexperienced observer might misinterpret this as mixed infection rather than as the simple presence of dead pneumococci in a classic infection. Further considerations include:

- *Is there a single most probable etiologic microorganism?* If so, is the morphology sufficiently characteristic to presume identification? Is there a specified antimicrobial drug for treatment of infections with this infectious agent? Is antimicrobial susceptibility testing necessary, or is identification of the suspected pathogen sufficient for empiric treatment?
- *Is the infection monomicrobial or polymicrobial?* Do morphotypes present characterize the source of the organisms? Can the mixture of organisms be characterized?
- *Examine more than one area of the smear.* More than one microorganism should be found if possible. It is rare not to be able to find more than one cell, because in an infection organisms are usually distributed throughout the specimen. Care should be taken in the interpretation of very low numbers of bacteria, especially in the absence of inflammation or necrosis and in specimens from non-sterile sites. Small numbers of organisms in samples from sterile sites must be seriously considered. However, additional smears can be made and examined if the likelihood of contamination is high.
- *Do not overinterpret the findings.* Specific diagnosis should be limited to a small number of instances in which the smear is classic in its presentation and the extent of infection is not an issue. If acid-fast bacteria are suspected, an acid-fast stain should be performed before an opinion is rendered. If a fungal element is suspected, a calcofluor white stain should be performed. Both of these follow-up stains can be performed on the decolorized, Gram-stained preparation.

Fig. 7.16 Amniotic fluid, cytocentrifuge preparation, Gram stain, light microscopy, medium-power view. Purulence, moderate. Local materials, moderate. No organisms seen. The presence of purulence (neutrophils or polymorphonuclear [PMN] leukocytes) indicates a process suspicious for infection. The absence of organisms in this normally sterile fluid is a critical observation. Squamous epithelial cells are local to this specimen type and confirm that the sample is amniotic fluid. The blue keratohyalin granules must not be mistaken for bacteria.

Grading or classifying materials

Microscopic examination can also immediately reveal that a specimen is unlikely to be helpful in diagnosis or culture management. The specimen may be just blood rather than infected material, or it may be oropharyngeal surface debris or some other normal surface material. Processing and culture interpretation of such nonrepresentative specimens may lead to delayed treatment because of a false-negative culture or to inappropriate antimicrobial therapy because of a false-positive culture from growth of normal biota or antimicrobial-altered biota.

Several grading or classification systems have been derived to aid the laboratory scientist in arriving at decisions relating to culturing the specimen or interpretation of growth from culture of a specimen. Most evaluations are aimed at specimens such as sputum, for which collection is complicated by contamination with throat and mouth biota because culture alone can be misleading. The objective is to separate the representative sample from the contaminated sample before culture or culture evaluation. Bartlett's Q scoring of sputum samples (Table 7.6) and the Murray-Washington method (Table 7.7) for contamination assessment document the association of 10 to 20 SECs per microscopic field at $\times 100$ magnification with unacceptable specimens and 10 to 25 PMN leukocytes per field at $\times 100$ magnification with significant specimens. Heineman's method emphasizes the ratio between SECs and PMN leukocytes.

In some cases, direct smear examination is a means for diagnosis. The Nugent scoring system for Gram-stained vaginal smears (see Table 16.4) is used to diagnose bacterial vaginosis. Stained smears are examined and scored for the presence of *Lactobacillus*, *Gardnerella*, and *Mobiluncus*

Table 7.6 Grading the quality of the clinical sample using Bartlett's Q score

Score	Average number of neutrophils per low-power field	Score	Average number of squamous epithelial cells per low-power field
0	0 (none)	0	0 (none)
+1	1–9 (few)	–1	1–9 (few)
+2	10–24 (moderate numbers)	–2	10–24 (moderate numbers)
+3	≥ 25 (many, numerous)	–3	≥ 25 (many, numerous)

Interpretation:
 Q score = (points for average number of neutrophils) + (points for average number of squamous cells)
 Minimum score = –3
 Maximum score = +3
 The higher the score, the better quality the specimen.

- A specimen with a composite score $\geq +1$ should be cultured.
- A sputum specimen from a leukopenic patient with ciliated respiratory epithelial cells should be cultured.
- A composite Q score that is 0 or negative is probably a superficial sample that may not be a reliable specimen and so is usually not cultured.

From Bartlett, R. C. (1974). *Medical microbiology: quality, costs and clinical relevance*. Malden, MA: John Wiley & Sons.

morphotypes. Observation of Gram-stained smears is more accurate than cultures in diagnosing bacterial vaginosis.

Many diagnostic microbiology laboratories use the documented observations related to SECs and PMN leukocytes but attempt to coordinate observations related to background materials, which consist of local materials, contaminating materials, and purulence, and to describe the relationship of microorganisms to these background materials. The body site of the sample, such as respiratory samples and wounds, and the classification of the smear together determine the extent of culture evaluation.

Contaminating materials

Contaminating materials (Fig. 7.17) are recognized as materials not coming from the collection site, not contributed by the inflammatory response from the tissues, or not likely to contain the infecting organism. They usually have been added to the specimen in the course of collection from or through a nonsterile area. The most bothersome contaminating

Table 7.7 Murray and Washington's grading system for assessing sputum sample quality

	Epithelial cells per low-power field	Leukocytes per low-power field
Group 1	>25	<10
Group 2	>25	10–25
Group 3	>25	>25
Group 4	10–25	>25
Group 5	<10	>25

Ideally, only samples that fall under groups 4 and 5 are suitable for culture. However, immune-suppressed individuals will have reduced numbers of leukocytes in their secretions as well when their cell counts diminish. Therefore the criteria have been revised so that the number of epithelial cells (>25 per low-power field) is a better indicator of mucosal or saliva contamination.

From Procop, G. W., et al. (2017). *Koneman's color atlas and textbook of diagnostic microbiology* (7th ed.). Philadelphia: Wolters Kluwer.

Fig. 7.17 Expecterated sputum smear, Gram stain, light microscopy (low-power view). Purulence, none. Contaminating bacteria and epithelial cells, heavy. No pathogens seen. The sample is saliva, not sputum. There could be several reasons for submission of this sample to the laboratory. The patient could have been poorly directed and simply "spit" into the collection container, or the patient's cough might not be productive of sputum. Another carefully collected sample of lower respiratory tree material should be submitted.

materials are materials containing microorganisms that will grow in culture and potentially confuse the culture interpretation. Expecterated sputum, from the lower lung airways and expelled through the mouth, is the most common contaminated specimen managed by the clinical laboratory.

Criteria

To signify presence of contaminating materials, fewer than 25 PMN leukocytes per low-power field (LPF) and more than 10 epithelial cells or mixed bacteria per LPF must be present.

Direct Gram smear report

The contaminating materials are quantitated as 1+ (light), 2+ (moderate), 3+ (moderately heavy), or 4+ (heavy).

Culture identification guidelines

In a specimen with contaminating material, organism identification should be limited to brief evaluation for *S. aureus*, streptococci or viridans streptococci, *Lactobacillus*, diphtheroids, and β -hemolytic streptococci. Gram-negative rods are reported as enterics (coliforms, non-lactose fermenters, or *Proteus* spp. [spreading colonies]), pseudomonads (oxidase-positive), pathogenic *Neisseria* spp. (identified), *Haemophilus* spp. (smear only), yeasts (note only), and any primary pathogen. When a specimen is regarded as containing contaminating material, a new culture using careful collection technique should be requested.

Antimicrobial susceptibility testing

No antimicrobial susceptibility testing is appropriate except on primary pathogens in specimens with contaminating material.

Local materials

Criteria

Direct smears from specimens containing local materials will likely yield fewer than 25 PMN leukocytes (white blood cells [WBCs]) per LPF and fewer than 10 contaminating epithelial cells per LPF are seen, along with cellular and fluid elements local to the area sampled.

The local constituents may differ as follows:

- Respiratory secretions (Fig. 7.18), including mucus, alveolar pneumocytes (macrophages), ciliated columnar cells, goblet cells, and occasionally metaplastic epithelial cells (smaller than normal SECs)
- CSF (Fig. 7.19) cellular elements
- Cavity fluid (Fig. 7.20) macrophages, a few mixed WBCs, mesothelial cells, and proteinaceous fluid
- Wounds—blood and proteinaceous fluids
- Amniotic fluid (see Fig. 7.16)—anucleate squamous cells and heavy proteinaceous fluid
- Cervix—mucus, columnar epithelial cells, goblet cells, metaplastic SECs, and leukocytes (vary with menstrual cycle)
- Prostatic secretions or semen—spermatozoa and mucus

Fig. 7.18 Expectorated sputum, smear, Gram stain, light microscopy (low-power view). Purulence, none. Local materials, moderate. Contaminating bacteria and epithelial cells, heavy. No pathogens seen. The bolus of sputum, consisting of mucus with entrapped alveolar macrophages, confirms that lower respiratory tract material is present. There is no evidence of an infectious process. The sputum is heavily coated by contaminating materials from the oropharynx or mouth. Contaminating organisms will grow in a routine sputum culture.

Fig. 7.19 Cerebrospinal fluid (CSF), cytocentrifuge preparation, Gram stain, light microscopy (high-power view). Purulence, moderate. No organisms seen. CSF is a sterile fluid and normally does not have purulence. The presence of neutrophils is critical. Careful observation for bacteria is mandatory. Acridine orange stain may be helpful in clinical settings in which bacteria are low in number and gram-negative. Cytocentrifuged sediments commonly have a concentration of organisms sufficient for routine microscopy ($\geq 10^5$ /mL).

Direct Gram smear report

Local microbial biota is quantitated as 1+ to 4+ (see the “Contaminating Materials” section earlier in this chapter).

Culture identification guidelines

The designation “usual microbiota” or a brief presumptive description of “colony-type growth” may be used (see the “Contaminating Materials” section earlier in this chapter).

Antimicrobial susceptibility testing

No antimicrobial susceptibility testing is appropriate on specimens with local material.

Fig. 7.20 Eye, vitreous aspirate, smear, Gram stain, light microscopy (high-power view). Purulence, light. Amorphous debris, moderate. Local materials, light. No organisms seen. This smear suggests that there has been an injury. The pigment has undergone phagocytosis and is seen within a large macrophage. Pigment must not be mistaken for bacteria, and bacteria must never be overlooked if mixed with local materials, such as pigment granules.

Purulence

Criteria

Greater than 25 PMN leukocytes (WBCs) per LPF and fewer than 10 epithelial cells per LPF are seen. Mucus or heavy proteinaceous material may be present. The clinical material can have a foul odor.

Direct Gram smear report

Only organisms intimately associated with the WBCs, mucus, or proteinaceous exudate are quantitated. The following system is used: 1+ (rare organisms per oil immersion field [OIF]), 2+ (few organisms per OIF), 3+ (moderate number per OIF), and 4+ (many per OIF). Contaminating materials are quantitated separately—should be 1+ (none or few).

Culture identification guidelines

Colony growth should be correlated with Gram-stained smear, as in the Case in Point. *S. pneumoniae* from viridans streptococci, β -hemolytic streptococci (Lancefield groups A, B, and D; C, F, and G, if indicated clinically), *S. aureus*, *H. influenzae*, pathogenic *Neisseria* spp., gram-negative bacilli, yeasts (*C. neoformans* only; note the presence of other genera), filamentous fungi (transparent tape preparation in biological safety cabinet), and other organisms are identified as indicated by smear findings.

Antimicrobial susceptibility testing

S. aureus, gram-negative nonfastidious bacilli, and other organisms should be tested for as appropriate or specifically requested. Studies have demonstrated that patients with microscopic evidence of purulence with positive cultures are more likely to receive antimicrobial therapy. However, microscopic evidence of purulence is not always associated with infection.

Mixed materials

Mixed materials consist of purulent exudate, contaminating materials, and local materials in a single smear.

Criteria

Fewer than 25 PMN leukocytes (WBCs) per LPF and fewer than 10 epithelial cells or contaminating bacteria per LPF are seen. Local secretions may also be present.

Direct Gram smear report

For mixed materials, only organisms intimately associated with purulent exudate are quantitated. The amounts of other elements, contaminating materials, and local materials also are quantitated.

Culture identification guidelines

A new culture may be requested for mixed specimens. A new specimen must be requested if the specimen shows the presence of purulence and the culture results cannot be interpreted. If a new culture specimen cannot be obtained, evaluation should proceed as for contaminating materials.

Antimicrobial susceptibility testing

Purulence guidelines should be used for testing organisms that appear significant.

Reports of direct examinations

Reports of the results of direct specimen examination should be made available as soon as they are completed. The availability of computer-managed reporting (i.e., hospital information systems) using direct physician access through computer terminals in patient care areas facilitates immediate reporting of results. Reports of direct examinations should be simple and include all information elements needed by the physician to understand the report. The report lists the type of material submitted and clearly states whether the observed microbes are of significance. An example of computer-managed microscopic reports from direct specimen examinations such as at The Ohio State University is shown in the samples given in [Box 7.1](#).

Only elements useful in characterizing the specimen should be included in the report. Interpretative comments also may be included when, on the basis of specimen type, background materials, and organism morphology, there is little doubt about the nature of the process or the offending infectious agent. All telephone reports of direct examinations should be recorded in the report. Once this stepwise evaluation of the smear has been completed, the information yielded, along with the clinical setting, allows reasonable management of infected patients until the subsequent steps of culture isolation, susceptibility testing, or antibody or antigen detection can occur.

BOX 7.1 Sample reports of direct microscopic examinations

Respiratory culture	Acc. no. XXXX
Source:	Sputum: expectorated
Microscopic	Purulence heavy Contaminating bacteria, yeasts, and epithelial cells heavy Gram-positive diplococci: consistent with pneumococci

Called to Dr. Doe at 8:00 PM 4/13/21

Respiratory culture	Acc. no. XXXXX
Source:	Sinus: ethmoid contents
Microscopic	Purulence moderate Local materials light Red blood cells present Gram-negative bacilli: consistent with <i>Pseudomonas</i>

Called to Dr. Doe at 11:35 AM 4/5/21

Case check 7.2

The foundation in the diagnostic microbiology laboratory, as in the Case in Point, is the ability to combine the rapid response of direct specimen examination with culture isolation and antimicrobial susceptibility testing to achieve the following:

- Confirm that the material submitted for study is representative.
- Identify the cellular components and debris of inflammation and establish the probability of infection.
- Identify specific infectious agents using direct visual detection of characteristic shape, size, and Gram stain reaction.
- Augment visual identification of microbes by use of specific stains, or antibody or gene-directed probes.
- Provide antimicrobial susceptibilities of isolated pathogens to guide treatment.
- Develop epidemiologic data.

Fig. 7.21 Sheep blood agar plate inoculated with expectorated sputum, 24-hour incubation with 5% carbon dioxide in air. Note heavy bacterial growth in the area of primary inoculation with thin trails of colonies (arrows) lacing the surface of the agar (see Fig. 7.22).

Fig. 7.22 Aspirated sputum, Gram stain, light microscopy (low-power view). Purulence, none. Local materials, moderate. Mucus present. Coiled nematode larvae (arrows). Morphology consistent with *Strongyloides stercoralis*. Impression: *Strongyloides* hyperinfestation syndrome.

Initiation of special handling for unsuspected or special pathogens

The direct microscopic examination of infected materials, along with specimen site and historic information, may suggest modifications in routine culture techniques to allow isolation of a suspected pathogen. Modifications might involve ordering other culture tests, adding special media, increasing incubation time, or changing incubation temperature or atmosphere. If recognition or suspicion of such pathogens does not occur from smear or history, the isolation of certain pathogens will not be made, and diagnosis will be delayed or missed.

Some pathogens do not grow in culture and are usually unsuspected. One is the nematode parasite *Strongyloides stercoralis*, which can be seen in the sputum and bronchoalveolar fluid of patients with hyperinfestation syndrome (Figs. 7.21 and 7.22). Visual recognition can lead to a request for stool examination for parasite load and prompt treatment. Untreated hyperinfestations are associated with death.

Pathogens that require special culture media for laboratory isolation can be recognized on smear and redirected for appropriate culture. Organisms such as *Legionella* spp., *Mycobacterium* spp., and *Bartonella* spp. must be placed on appropriate media for culture confirmation of infection.

Quality control in direct microscopic interpretations

QC considerations such as the quality of specimens submitted, how well the staining procedure was performed, and the adequacy of culture interpretation can be monitored using the results of direct examination. The quality of the staining reagents and proper staining technique can be assessed using organisms such as *S. aureus* and *Escherichia coli* to serve as the positive and negative controls, respectively. QC practice that monitors both the smear and the culture interpretation should be an ongoing work activity. Correlation between the two results should be made for each patient. Explanations for discrepant results should be

sought within the work material. This repeated inspection of results enables each observer to practice self-education and improve observation skills. Review of these QC activities allows corrections to be made in specimen collection, specimen management, materials and procedure administration, and culture management.

Quality improvement activities often are suggested by the results of QC monitoring of direct specimen examination. For example, it may be documented that sputum specimens of poor quality are consistently submitted from certain physicians' offices, clinics, or nursing stations in the hospital. This observation becomes the basis for planning corrections that move outside the laboratory to involve the population of patients served.

Examples of sample observations and reports

Additional examples of direct observations and the associated reports and comments are given in [Plates 1 to 61](#). Practice to determine whether you can make a similar report using only the observation provided. Then read each report to see whether you obtain similar impressions of the specimen and pathogen from the observation and written report.

POINTS TO REMEMBER

Direct microscopy of materials submitted to the laboratory for identification of infectious organisms offers the first, last, and best opportunity to do the following:

- Suspect probable infection.
- Confirm the diagnostic quality of the specimen submitted.
- Recognize "classic" organism morphotypes associated with infection.
- Recognize pathogens that will not grow in culture or the culture type requested, thus requiring a different diagnostic approach.
- Provide a "stat" laboratory response to serious infection.
- Provide a pathway to confirm the suspected cause of infection

LEARNING ASSESSMENT QUESTIONS

- c. Calcofluor white stain
- d. All of the above
4. Which of the following stains is best used to detect mycobacterial organisms in clinical samples?
 - a. Gram
 - b. Giemsa
 - c. Acid-fast
 - d. India ink
5. Calcofluor white is a colorless dye that binds with which of the following structures?
 - a. Chitin
 - b. Mycolic acid
 - c. Peptidoglycan layer
 - d. Metachromatic granules
6. Cyto centrifugation is an excellent method for which of the following types of samples?
 - a. Heavily contaminated
 - b. Nonviscous fluids
 - c. Thick purulent material
 - d. Bloody specimens
7. Which of the following is indicative of a monobacterial type of infection based on the direct microscopic examination of the clinical sample?
 - a. Keratohyalin granules
 - b. Inflammatory debris
 - c. Squamous epithelial cells
 - d. A single morphotype of microorganism
8. In a Wright-Giemsa-stained smear, bacteria would appear as which of the following colors?
 - a. Red
 - b. Green
 - c. Blue
 - d. Orange
9. In preparing smears from swabs, which of the following should be followed?
 - a. Inoculate the solid culture media first with the swab before preparing the smear on the slide.
 - b. Roll the swab back and forth over the selected area on the slide.
 - c. Rub the swab back and forth spreading the material across the desired area on the slide.
 - d. Place the swab in a broth medium before applying the material on the slide.
10. Which of the following is the value of a direct microscopic examination for microorganisms in clinical samples?
 - a. Results may confirm or reject the physician's initial diagnosis.
 - b. Useful results keep the treatment plan moving in the right direction when delivered in a timely manner.
 - c. Direct smear examination results can be correlated with culture results.
 - d. All of the above.
11. When examining the Gram stain quality control slides, you note that *S. aureus* and *E. coli* stained pink. Which of the following is likely?
 - a. The results are correct.
 - b. The two smears are under-decolorized.
 - c. The *S. aureus* smear is over-decolorized.
 - d. The *E. coli* smear is over-decolorized.

1. Direct smear examination of clinical samples is a rapid means to identify presumptively the etiologic agents of infectious disease. True or false?
2. The presence of an infectious disease process can be assessed on a direct smear based on which of the following?
 - a. The presence of numerous inflammatory cells
 - b. The morphology of the bacteria present
 - c. Gram stain reaction of bacteria present
 - d. The presence of numerous epithelial cells
3. Which of the following stains may be used for direct smear examination?
 - a. Gram stain
 - b. Acid-fast stain

Direct examination showing local and contaminating materials

PLATE 1 Aspirated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, none. Local materials, moderate. No organism seen. The alveolar macrophages and mucus (pink-stained background) are the local materials from the tracheobronchial tree. This smear confirms that sputum was sampled, and there is no suspicion of infection and no evidence of significant contamination. Routine culture of this specimen can grow insignificant oral biota because culture is more sensitive than direct examination.

PLATE 3 Bronchoalveolar lavage, cytocentrifuge smear, Gram stain, light microscopy (high-power view). Purulence, heavy. No organisms seen. Local materials, black particulate debris (*arrow*). This size and type of carbon particles is commonly seen in respiratory samples in small amounts and is usually not noted in a smear report.

PLATE 2 Trauma eye, vitreous aspirate, smear, Gram stain, light microscopy (high-power view). Purulence, none. No organisms seen. Local materials, light. The light protein background and the pigment-containing cell are normal material local to the vitreous of the eye. This local material confirms that the sample is representative. The ability to see this brown pigment cell in smear material is related to the eye trauma. The important emphasis is the absence of purulence.

PLATE 4 Bronchoalveolar lavage, cytocentrifuge smear, Gram stain, light microscopy (high-power view). Purulence, none. No organisms seen. Local materials, heavy black particulate debris (*arrows*). This small carbon particles seen prominently in respiratory samples can be associated with smoking crack cocaine. The gross sample usually has a gray appearance. Black particulate debris should not be confused with gram-positive cocci.

PLATE 5 Bronchoalveolar lavage, cytocentrifuge smear, Gram stain, light microscopy (high-power view). Purulence, none. No organisms seen. Local materials, black particulate debris (BPD) moderate. This BPD is irregular in shape and usually varies in size (*arrows*). This type of carbon debris is commonly associated with smoke inhalation from house or other types of fires. In the early phase of smoke inhalation, much of the BPD is extracellular. Later, much of the debris is intracellular within phagocytes. The golden macrophage present contains yellow material associated with cigarette smoking.

PLATE 7 Bronchoalveolar lavage, cytocentrifuge smear, Gram stain, light microscopy (high-power view). Purulence, none. No organisms seen. Local materials, alveolar macrophages containing golden yellow to Gram's safranin-colored chunky, irregular particles consistent with hemosiderin (*arrows*). This type of large-particle hemosiderin deposition within lung phagocytes is commonly associated with blood in the lung as seen in heart failure or aspirated blood from large-volume nosebleeds. Blood and hemosiderin in a Gram-stained smear make smear viewing more difficult.

PLATE 6 Bronchoalveolar lavage, cytocentrifuge smear, Gram stain, light microscopy (high-power view). Purulence, none. No organisms seen. Local materials, alveolar macrophages containing very small, light to golden yellow, refractile but not polarizing particles (*arrow*). These small, fine particles can be hemosiderin, sometimes deposited as small particles or other fine particles from the environment. Such refractile particles are not usually reported except in response to specific questions from the patient's physician.

Direct examination in common bacterial infections

PLATE 8 Expectorated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, heavy. The presence of gram-positive diplococci, intracellular morphology suggests an antimicrobial agent effect. *Impression:* pneumococcal disease. This is a typical smear presentation of a treated but unresolved pneumococcal pneumonia. Neutrophils cover the field, the diplococci are largely intracellular and partially digested, and the background amorphous material is gone. Routine bacterial culture of this sample may be negative for typical colonies of *S. pneumoniae*. A few colonies may be found by a careful search among the contaminating normal biota colonies.

PLATE 10 Wound, smear, Gram stain, light microscopy (medium-power view). Purulence, moderate. Amorphous debris, moderate. Gram-positive cocci, chains, extracellular. *Impression:* streptococcal disease. The presence of typical chains of *Streptococcus* on a background showing purulence with poorly preserved polymorphonuclear (PMN) leukocytes and amorphous debris is suggestive of hemolytic streptococci with tissue cytotoxicity. Routine bacterial culture yielded a pure growth of *S. pyogenes*.

PLATE 9 Aspirated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, light. Amorphous debris, heavy. Gram-positive cocci, pairs, encapsulated, extracellular. Initial antimicrobial therapy can be directed toward streptococci and staphylococci (*Stomatococcus*). Routine bacterial culture isolated a pure growth of an encapsulated strain of *Streptococcus pyogenes*. The heavy amorphous background is protein-rich edema fluid from the capillary bed damaged by *S. pyogenes* toxins. The patient subsequently died of the infection despite a correct diagnosis and appropriate antimicrobial therapy.

PLATE 11 Expectorated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, light. Local materials, moderate. Gram-positive cocci, pairs, groups, intracellular, and extracellular. *Impression:* staphylococcal disease. Smear morphology is typical for staphylococci, but no staphylococcal colonies were present on the culture plates. *Stomatococcus mucilaginosus* colonies were present in high numbers. Careful correlation between direct and culture examinations demonstrated this organism to be the probable cause of infection. The presumptive report implying or suggesting staphylococci followed by a negative culture report without explanation raises doubts about the competence of the laboratory.

Direct examination in gram-positive bacillary infections

PLATE 12 Amniotic fluid, cytocentrifuge, Gram stain, light microscopy (medium-power view). Purulence, light. Local materials, moderate. Gram-positive bacilli, small. Morphology consistent with *Listeria monocytogenes*. Impression: congenital listeriosis.

PLATE 15 Amniotic fluid, cytocentrifuge preparation. Gram stain, light microscopy (high-power view). Purulence, light. Local materials, moderate. Gram-positive bacilli, medium, long, intracellular. Morphotype consistent with *Lactobacillus* spp. Impression: amnionitis.

PLATE 13 Expectorated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, moderate. Local materials, moderate. Gram-positive bacilli, diphtheroid. Morphology suggests coryneform infection. Routine bacterial culture grew *Corynebacterium pseudodiphtheriticum*.

PLATE 16 Amniotic fluid, smear, Gram stain, light microscopy (medium-power view). Purulence, light. Local materials, moderate. Gram-positive bacilli, large. Morphology consistent with *Clostridium perfringens*. Impression: amnionitis.

PLATE 14 Urine, cytocentrifugation, Gram stain, light microscopy (medium-power view). Purulence, moderate. Gram-positive bacilli, medium, long, chaining. Morphology consistent with *Lactobacillus* spp. Impression: cystitis.

PLATE 17 Vaginal culture, colony from blood agar, smear, Gram stain, light microscopy (high-power view). Gram-positive bacilli, diphtheroid, variably Gram staining. Morphotype consistent with *Gardnerella vaginalis* (see Plate 18).

PLATE 18 Amniotic fluid, smear, Gram stain, light microscopy (high-power view). Local materials, heavy. Gram-positive bacilli, diphtheroid, variably Gram staining. Morphotype consistent with *Gardnerella vaginalis*. Impression: amnionitis.

Direct examination in uncommon gram-positive bacilli

PLATE 19 Abscess aspirate, smear, acid-fast stain (Ziehl-Neelsen), light microscopy (medium-power view). Purulence, moderate. Acid-fast bacilli, numerous (arrow). Mycobacterial cultures grew *Mycobacterium kansasii*.

PLATE 20 Expecterated sputum, concentrated smear, fluorochrome acid-fast stain, fluorescent microscopy (medium-power view). Typical acid-fast bacteria, numerous. Impression: mycobacterial disease. The patient had been placed in respiratory isolation after physical examination and history taking, and antituberculosis therapy was immediately begun after receipt of the direct examination report. *Mycobacterium tuberculosis* was identified from culture.

PLATE 21 Expecterated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, light. Local materials, light. Amorphous debris, moderate. Gram-positive bacilli, medium, beaded (arrow). Follow-up acid-fast stain positive. Chest radiograph with right lung upper lobe mass. Culture yielded *Rhodococcus equi*.

PLATE 22 Blood culture, sediment smear, Gram stain, light microscopy (medium-power view). Blood. Gram-positive bacilli, branched, beaded. Morphology consistent with *Actinomyces* or *Propionibacterium* spp. Culture isolation of *Actinomyces israelii*.

PLATE 23 Expectorated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, light. Local materials, light. Amorphous debris, moderate. Gram-positive bacilli, branched, beaded. Morphotype consistent with *Nocardia* or *Actinomyces*.

PLATE 24 Expectorated sputum, smear, partial acid-fast stain, light microscopy (medium-power view). Partially acid-fast bacilli, branched, beaded (arrow). Morphology consistent with *Nocardia* spp. *Impression:* nocardiosis.

Direct examination in gram-positive bacilli with filaments and branches

PLATE 25 Jaw abscess aspirate, smear, Gram stain, light microscopy (low-power view). Purulence, heavy. Granules present. Suspicious for *Actinomyces* spp. (see Plate 27).

PLATE 27 Cutaneous sinus tract aspirate, smear, Gram stain, light microscopy (high-power view). Purulence, heavy. Gram-positive bacilli, filamentous, beaded, branched, partial acid-fast stain-negative. Morphology consistent with *Actinomyces* spp. *Impression:* actinomycosis.

PLATE 26 Jaw abscess aspirate, smear, Gram stain, light microscopy (high-power view). Purulence, heavy. Gram-positive bacilli, filamentous, beaded, branched, partial acid-fast stain negative. Morphology consistent with *Actinomyces* spp. *Impression:* actinomycosis (lumpy jaw).

PLATE 28 Cutaneous sinus tract aspirate, colonies on an anaerobic blood agar plate. Mixed colony morphotypes. Molar tooth colonies. Morphology consistent with *Actinomyces israelii*. *Impression:* mixed anaerobic infection—actinomycosis.

PLATE 29 Expecterated sputum, chalky white colonies on plate with 5% sheep blood agar at 5 days' incubation. Routine sputum culture. Morphology consistent with *Nocardia*, *Nocardiosis*, or *Streptomyces* spp.

PLATE 31 Surgical biopsy of abnormal area in jawbone, smear, Gram stain, light microscopy (high-power view). Amorphous debris, heavy. Gram-positive bacilli, filamentous, beaded, branched, partial acid-fast stain-negative (*arrows*). Morphology suggests actinomycete. Aerobic and anaerobic cultures negative.

PLATE 30 Sinus tract granule, crush-pull smear, Gram stain, light microscopy (high-power view). Amorphous debris, moderate. Gram-positive bacilli, filamentous, beaded, branched, partial acid-fast stain-negative. Gram-positive bacilli, regular. Gram-negative bacilli, small. Gram-positive cocci. Morphology suggests mixed anaerobic infection with actinomycetes. *Impression*: actinomycosis. Culture isolation of *Actinomyces naeslundii*.

Direct examination in selected gram-negative bacterial infections

PLATE 32 Expectorated sputum, smear, Gram stain, light microscopy (medium-power view). Mixed materials, type I, layered. Contaminating bacteria and epithelial cells, moderate. Purulence, light. Gram-negative diplococci (arrows). Morphology suggests pathogenic *Neisseria* or *Moraxella* spp. Routine bacterial culture isolated *Moraxella catarrhalis*.

PLATE 34 Expectorated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, heavy. Local materials, moderate. Gram-negative bacilli, small, pleomorphic, intracellular, extracellular (arrow 1). Gram-positive diplococci, encapsulated, intracellular, extracellular (arrow 2). Morphology consistent with *H. influenzae* and *S. pneumoniae*. Impression: polymicrobial infection.

PLATE 33 Expectorated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, moderate. Local materials, moderate. Gram-negative diplococci, intracellular, extracellular (arrows). Morphology suggests pathogenic *Neisseria* or *Moraxella* spp. Routine bacterial culture isolated *Neisseria meningitidis*.

PLATE 35 Bronchoalveolar lavage, cytocentrifuge preparation, Wright-Giemsa stain, light microscopy (high-power view). Purulence, none. Lymphocytes present. Local materials, moderate. Small bacilli (arrow), numerous (see Plate 36).

PLATE 36 Bronchoalveolar lavage, cytocentrifuge preparation, Gram stain, light microscopy (high-power view). Purulence, none. Lymphocytes present. Local materials, moderate. Gram-negative bacilli (arrow), small (see Plate 37).

PLATE 38 Bronchoalveolar lavage, cytocentrifuge preparation, Wright-Giemsa stain, light microscopy (high-power view). Purulence, none. Lymphocytes present. Local materials, moderate. Ciliated columnar epithelial cells with numerous small bacilli adherent to cilia (arrows). Morphology consistent with *Bordetella pertussis*. Impression: whooping cough (pertussis).

PLATE 37 Bronchoalveolar lavage, cytocentrifuge preparation, Wright-Giemsa stain, light microscopy (high-power view). Purulence, none. Lymphocytes present. Local materials, moderate. Bacilli (arrows), small.

Direct examination in selected gram-negative bacillary infections

PLATE 39 Cerebrospinal fluid, drop smear, Gram stain, light microscopy (high-power view). Purulence, moderate. Gram-negative coccobacilli, chains (arrow). Morphotype suggests *Bacteroides* spp. *Impression:* Gram-negative bacillary meningitis.

PLATE 42 Bronchoalveolar lavage, cytocentrifuge preparation, direct fluorescent antibody. *Legionella pneumophila*, polyvalent antisera, fluorescent microscopy (high-power view). Immunofluorescence-positive. *Impression:* Legionnaires' disease.

PLATE 40 Amniotic fluid, cytocentrifuge preparation, Gram stain, light microscopy (high-power view). Purulence, moderate. Local materials, moderate. Gram-negative coccobacilli (arrow 1). Gram-negative bacilli, filamentous, medium, fusiform (arrow 2). Morphology suggests gram-negative bacillary anaerobic infection. *Impression:* amnionitis, mixed anaerobic bacteria.

PLATE 43 Expecterated sputum, smear, Gram stain, light microscopy (medium-power view). Purulence, light. Local materials, light. Mucus, moderate. Gram-negative bacilli, medium. *Impression:* enteric bacillary infection.

PLATE 41 Bronchoalveolar lavage, cytocentrifuge preparation, Gram stain, light microscopy (high-power view). Purulence, moderate. Local materials, light. Gram-negative bacilli, small, intracellular within phagocytic vacuoles (arrow).

PLATE 44 Urine, direct drop smear, Gram stain, light microscopy (medium-power view). Purulence, heavy. Gram-negative bacilli, medium (arrow 1). Gram-positive cocci (arrow 2). Urine culture grew *Escherichia coli* and *Enterococcus faecalis*. The smear is consistent with a bacterial density of 10^5 colony-forming units per milliliter of urine.

PLATE 45 Decubitus skin ulcer, smear, Gram stain, light microscopy (high-power view). Purulence, moderate. Amorphous debris, heavy. Gram-negative bacilli, medium, encapsulated. Yeast. Morphology suggests *Klebsiella pneumoniae*. Impression: enteric bacillary disease.

PLATE 48 Peripheral blood, smear, Gram stain, light microscopy (high-power view). Local materials, moderate. Gram-negative bacillus, medium, with prominent bipolar staining (arrow). Suspicious for *Yersinia pestis*. Impression: bubonic plague.

PLATE 46 Expectorated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, moderate. Mucus, moderate. Gram-negative bacilli, aberrant, encapsulated (arrow). Morphology suggests antimicrobial agent-affected *Klebsiella pneumoniae*. Impression: enteric bacillary disease, partially treated.

PLATE 49 Expectorated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, none. Local materials, none. Mucus, present. Gram-negative bacilli, regular (arrow). Morphotype suggests *Pseudomonas aeruginosa*. Impression: pseudomonal infectious disease.

PLATE 47 Peripheral blood, smear, Wright-Giemsa stain, light microscopy (medium-power view). Bacilli, medium, bipolar staining (arrow) (see Plate 48).

PLATE 50 Expectorated sputum, smear, Gram stain, light microscopy (high-power view). Purulence, light. Local materials, none. Mucus, present. Gram-negative bacilli, regular, enveloped in prominent slime layer (arrow). Morphotype suggests mucoid *P. aeruginosa*. Impression: pseudomonal infectious disease.

PLATE 51 Amniotic fluid, cytocentrifuge preparation, Gram stain, light microscopy (high-power view). Purulence, light. Local material, moderate. Gram-negative bacilli, fusiform (arrow). Morphology suggests *Fusobacterium* spp. Impression: amnionitis, anaerobic bacteria.

PLATE 53 Colonies on sheep blood agar, subculture from blood culture broth, smear, Gram stain, light microscopy (high-power view). Local material, light. Gram-negative bacilli with spirals, gull wings (arrows). Morphology suggests *Campylobacter* spp.

PLATE 52 Amniotic fluid, cytocentrifuge preparation, Gram stain, light microscopy (high-power view). Purulence, moderate. Local material, moderate. Gram-negative bacilli, medium and long forms (arrows). Morphology suggests *Fusobacterium* spp. Impression: amnionitis, anaerobic bacteria.

PLATE 54 Amniotic fluid, drop smear, Gram stain, light microscopy (high-power view). Purulence, moderate. Local materials, moderate. Gram-negative bacilli, spiral (arrow). Impression: amnionitis.

Direct examination in polymicrobial infections

PLATE 55 Buccal space abscess, smear, Gram stain, light microscopy (high-power view). Purulence, heavy. Gram-positive cocci, pairs, chains. Gram-positive bacilli, small, diphtheroid, medium, branched. Gram-negative coccobacilli. Morphology suggests polymicrobial infection from mouth biota. *Impression:* polymicrobial infection, oropharyngeal biota.

PLATE 57 Cervix, smear, conventional Gram stain, light microscopy (medium-power view). Purulence, heavy. Gram-positive cocci, pairs. Gram-negative coccobacilli. Gram-negative filaments. Trichomonads (arrow, *Trichomonas vaginalis*; compare with Plate 58). *Impression:* trichomoniasis with mixed aerobic and anaerobic bacterial biota.

PLATE 56 Maxillary sinus aspirate, smear, Gram stain, light microscopy (high-power view). Purulence, heavy. Gram-positive cocci, chains. Gram-negative coccobacilli, large masses. Morphotype suggests mixed infection with streptococci and anaerobic gram-negative coccobacilli. *Impression:* polymicrobial infection, aerobic and anaerobic species.

PLATE 58 Cervix, smear, enhanced Gram stain, light microscopy (medium-power view). Purulence, heavy. Gram-positive cocci, pairs. Gram-negative coccobacilli. Gram-negative filaments. Trichomonads (arrow, *Trichomonas vaginalis*). *Impression:* trichomoniasis with mixed aerobic and anaerobic bacterial biota.

PLATE 59 Eye, vitreous aspirate, smear, Gram stain, light microscopy (medium-power view). Purulence, moderate. Gram-positive diplococci, encapsulated, lancet-shaped (*arrow 1*). Gram-negative bacilli, small, pleomorphic (*arrow 2*). Morphotype suggests mixed infection with *S. pneumoniae* and *H. influenzae*. *Impression*: vitritis, mixed infection.

PLATE 61 Drainage, ruptured appendix, smear, light microscopy (high-power view). Purulence, heavy. Gram-positive bacilli, large and medium forms. (*arrow 1*). Gram-negative bacilli (*arrow 2*). Morphology suggests polymicrobial infection with fecal microbiota. *Impression*: polymicrobial infection, fecal biota.

PLATE 60 Wound, smear, Gram stain, light microscopy (medium-power view). Purulence, heavy. Gram-negative bacilli, medium (*arrow 1*). Gram-positive cocci, pairs (*arrow 2*). *Impression*: enteric bacillary infectious disease.

Use of colony morphology for the presumptive identification of microorganisms

Connie R. Mahon

CHAPTER OUTLINE

Importance of colony morphology as a diagnostic tool, 170

Initial observation and interpretation of cultures, 170

Gross colony characteristics used to differentiate and presumptively identify microorganisms, 173

Hemolysis, 173

Size, 174

Form or margin, 174

Elevation, 175

Density, 175

Color, 176

Consistency 176

Pigment 176

Odor 177

Colonies with multiple characteristics, 177

Growth of microorganisms in liquid media, 177

Bibliography, 182

- “Diphtheroids” and staphylococci
- Lactose fermenters and nonlactose fermenters
- “Swarming” *Proteus* species and other members of the order Enterobacterales

KEY TERMS

α-Hemolysis	Lactose fermenter
β-Hemolysis	Margin
Brittle	Nonlactose fermenter
Butyrous	Opaque
Colony morphology	Pigment
Consistency	Rhizoid
Creamy	Smooth
Density	Streamers
Elevation	Swarming
<i>Escherichia/Citrobacter</i>-like organisms	Transillumination
Fastidious	Translucent
Filamentous	Transparent
Hemolysis	Turbidity
<i>Klebsiella/Enterobacter</i>-like organisms	Umbilicate
	Umbonate

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe how growth on blood, chocolate, and MacConkey agars is used in the preliminary identification of bacterial isolates.
2. Differentiate α -hemolysis from β -hemolysis on sheep blood agar medium.
3. Associate the colony characteristics exhibited on blood, chocolate, and MacConkey agars with the microscopic findings on direct smear and use the information in the presumptive identification of microorganisms.
4. Using colony morphology, differentiate among the following microorganisms:
 - Staphylococci and streptococci
 - *Streptococcus agalactiae* and *Streptococcus pyogenes*
 - *Neisseria* spp. and staphylococci
 - Yeasts and staphylococci

Case in point

An exudate from a sacral decubital ulcer on a 65-year-old hospital inpatient was cultured on sheep blood agar (SBA), chocolate (CHOC) agar, and MacConkey (MAC) agar. Direct smear examination showed many white blood cells, a moderate number of gram-positive cocci in pairs and clusters, and a few gram-negative bacilli. After overnight incubation, three colony morphotypes were visible on the SBA and CHOC media. On SBA, the first was a moderate growth of a medium-sized β -hemolytic colony that was off-white with a creamy-buttery texture. The second colony was also β -hemolytic but larger, mucoid, and gray. The third colony type was large, gray, and

mucoid, similar to the second, but was nonhemolytic. The MAC agar showed two colony morphotypes—a light growth of dark pink, dry-looking colonies with a surrounding pink precipitate and a few clear colonies. Based on the Gram stain results and colony characteristics of the isolates, appropriate biochemical tests and antimicrobial susceptibilities were performed to identify the causative agents of the ulcer.

Issues to consider

After reading the patient's case history, consider:

- The direct smear examination findings and how they correlate with the colony morphology of isolates on each culture medium
- The colony morphology of isolates and how it is used to presumptively identify microorganisms
- The colony morphology of each isolate in differentiating between pathogenic and nonpathogenic microorganisms

The importance of the ability to recognize and describe the **colony morphology** (colony characteristics) of microorganisms on culture media and interpretation of Gram-stained smears from clinical specimens cannot be overemphasized. Although Gram-stained smears provide initial identification of microorganisms by microscopic characterization, description of the physical growth characteristics of microorganisms on laboratory media facilitates the initial identification process.

Close your eyes, and imagine the physical characteristics of a person you know well. The person's height, weight, shape, color and style of hair, eyes, freckles, and color of skin as well as voice or laugh may make that person distinctive in a crowd or when his or her back is facing you. In the same manner, many microorganisms have specific characteristics that distinguish them in a crowd of other genera or species.

This chapter discusses the characteristics that are used to describe colony morphology of certain groups of organisms and how these characteristics are used to differentiate one species from a closely related species and one genus from another. It also presents how the characterization of colonies on culture media and the findings on stained direct smears facilitate presumptive identification of commonly isolated organisms.

Importance of colony morphology as a diagnostic tool

The ability of the microbiologist to provide a presumptive identification by colony morphology extends the usefulness of colony characterization beyond a pathway to organism identification and ultimately may include the following:

- **Provide a presumptive identification to the physician.** Even in this age of rapid identification systems, incubation times and procedures can be protracted. In a critical situation, the microbiologist makes an educated judgment about the presumptive identity before performing diagnostic identification procedures.

- **Enhance the quality of patient care through rapid reporting of results and by increasing the cost-effectiveness of laboratory testing.** This may best be illustrated by using sputum cultures as an example. The upper respiratory tract contains many indigenous microorganisms, and to identify every organism in culture would be a time-consuming, cost-prohibitive, and insurmountable task. Microbiologists must be able to differentiate potential pathogens from the “usual” inhabitants (microbiota) of the upper respiratory tract and direct the diagnostic workup toward only potential pathogens. Potential pathogens are presumptively identified by colony characteristics, and preliminary reporting initiates immediate therapy.
- **Play a significant role in quality control, especially of automated procedures and other commercially available identification systems.** When commercial and automated systems are used, a mixed inoculum (polymicrobial, containing more than one species) produces a biochemical test result or erroneous interpretation of reactions that significantly alters the identification (see [Chapter 9](#)). The ability of the microbiologist to determine whether the inoculum is mixed and to ascertain whether the results generated by a commercial or automated system correlate with the suspected identification of the organism is an important component of quality control that is accomplished by recognizing organisms by their colony characteristics.

Initial observation and interpretation of cultures

Primary plating refers to inoculation of the clinical specimen onto laboratory culture media. As previously described in [Chapter 1](#), there are various types of culture media and environmental conditions used in the clinical microbiology laboratory to recover microbial pathogens in clinical samples. The microbiologist must be aware of how each medium functions, the ingredients present, inhibitory agents added in the medium, and possibly growth factors to support and maximize recovery of pathogens. Some laboratory media are selective in that agents are added to inhibit the growth of certain species. This allows better recovery of pathogenic bacteria that are resistant to the inhibitory agents. Some media are differential, permitting the differentiation of bacterial strains based on colony morphology. Differential media are based on the ability of some bacteria, and not others, to utilize a substrate that often produces a change in the pH that is detected by a change in the color of a pH indicator. The ability to determine which organisms grow on selective and differential media aids the microbiologist in making an initial distinction between gram-positive and gram-negative isolates. SBA and CHOC agar, for example, support the growth of various **fastidious** organisms (hard to grow and require additional growth factors) as well as non-fastidious organisms, both gram-positive and gram-negative bacteria.

Clinical microbiology laboratories establish culture plating media protocols that guide microbiologists as to which

media must be inoculated with different clinical specimens (see [Chapter 6](#) for a discussion on specimen collection and processing). For example, specimens such as wounds are plated on culture media such as SBA, CHOC agar, and MAC agar to recover both gram-positive and gram-negative organisms that may be present. Because enteric pathogens are expected in a stool sample, a highly selective medium such as Hektoen enteric is added to MAC agar to enhance recovery of enteric pathogens (e.g., *Salmonella*). [Table 8.1](#) lists some of the media commonly used in a clinical microbiology laboratory along with the key ingredients and their common uses (see [Appendix B on Evolve](#) for a more complete list of laboratory culture media).

Generally, microbiologists observe the colony morphology of organisms isolated on primary culture after 18 to 24 hours of incubation. This process is commonly referred to as *plate reading*, a comparative examination of the colony morphology of microorganisms growing on various culture media. During this process, each type of agar plate

is examined in relationship to the other. As a set of culture media, comparative colony examination of growth from a specimen occurs. To illustrate, generally, organisms that grow on SBA also grow on CHOC agar, but not all organisms that grow on CHOC agar grow on SBA. Although SBA supports fastidious organisms, highly fastidious species, such as *Haemophilus* spp. and *Neisseria gonorrhoeae*, do not grow on it. CHOC agar provides additional nutrients to support highly fastidious organisms such as *Haemophilus* spp. and *N. gonorrhoeae*. Therefore, a gram-negative bacillus that grows on CHOC agar but not on SBA or MAC agar would be suspected to be *Haemophilus* spp., whereas gram-negative diplococci with the same growth pattern would be suspected to be *N. gonorrhoeae* ([Fig. 8.1](#)). The microbiologist is then able to provide a presumptive identification and determine how to proceed in identifying the isolated organisms. Bacterial colonies selected for further testing will be inoculated to other plates, a process referred to as *subculturing*.

Table 8.1 Commonly used media in the clinical microbiology laboratory

Medium	Key ingredients	Uses
Anaerobic blood agar, CDC	Intact sheep red blood cells, vitamin K, yeast extract	Nutritious medium for the isolation and subculturing of obligate anaerobic bacteria
Campy-CVA	<i>Brucella</i> agar base medium; antimicrobials cefoperazone, vancomycin, and amphotericin B; 5% sheep blood agar	Selective for the isolation of <i>Campylobacter</i> spp. in stool specimens
Chocolate agar	GC agar base (provides casein and meat peptones) Hemolyzed sheep red blood cells or supplemented with 2% hemoglobin and NAD or IsoVitaleX (BD BBL, Cockeysville, MD)	Primary plating and subculturing of fastidious bacteria, e.g., <i>Haemophilus</i> and pathogenic <i>Neisseria</i> spp.
Columbia colistin-nalidixic acid (CNA) agar	Columbia agar base, antimicrobials colistin and nalidixic acid 5% sheep red blood cells	Selective isolation of gram-positive cocci, e.g., staphylococci and streptococci
Gram-negative (GN) broth	Peptone-base broth with dextrose (glucose) and mannitol Sodium citrate, and sodium deoxycholate	Selective enrichment broth medium for isolation of gram-negative enteric bacteria, <i>Salmonella</i> and <i>Shigella</i> spp.
Hektoen enteric agar	Lactose, salicin, and sucrose, bile salts to inhibit growth of gram-positive bacteria and many nonpathogenic enteric bacteria	A selective and differential medium for the primary plating of stool specimens to aid in the recovery of intestinal pathogens (e.g., <i>Salmonella</i>)
Lowenstein-Jensen medium	Potato flour, egg and glycerol Asparagine to enhance niacin production Malachite green inhibits growth of other bacteria	Used to cultivate <i>Mycobacterium</i> spp.
MacConkey agar	Lactose and bile salts, the low concentration of bile salts inhibits gram-positive bacteria but permits the growth of many gram-negative bacteria	A selective and differential medium for the isolation of gram-negative bacteria; used for primary plating and subculturing
Modified Thayer-Martin agar	Chocolate agar base containing the antimicrobial agents vancomycin, colistin, trimethoprim, and nystatin	A selective primary plating medium for recovery of <i>Neisseria gonorrhoeae</i> and <i>Neisseria meningitidis</i>
Sabouraud dextrose agar	Dextrose (glucose), antimicrobials can be added to inhibit bacteria	Primary plating and subculturing of fungi
Sheep blood agar	Tryptic soy agar base 5% sheep red blood cells	Primary plating and subculturing of most medically important bacteria
Thioglycollate broth	Contains many nutritive factors, including glucose, casein, yeast, beef extracts, and vitamins Thioglycollate, cystine, and sodium sulfite as reducing agents	Enriched broth medium Supports growth of aerobes, anaerobes, microaerophilic and fastidious organisms

CDC, Centers for Disease Control and Prevention; NAD, nicotinamide adenine dinucleotide.

Case check 8.1

As illustrated in the Case in Point, the Gram-stained smear showed gram-positive cocci and gram-negative bacilli. Three colony morphotypes were observed on SBA; one was identified as gram-positive cocci, and the other were two different gram-negative species. The direct Gram-stained smear will not allow distinctions between the two different gram-negative bacteria. Similar colony morphology observations, except for hemolysis, was made on CHOC agar.

Whereas MAC agar supports most gram-negative rods, especially the Enterobacterales, it inhibits growth of gram-positive organisms and some fastidious gram-negative organisms, such as *Haemophilus* and *Neisseria* spp. Growth on SBA and CHOC agar but not on MAC agar is indicative of a gram-positive isolate or of a fastidious gram-negative bacillus or coccus.

On SBA and CHOC agar, gram-negative rods often produce large colonies that appear gray and sometimes mucoid, and if

Fig. 8.1 Clockwise from top: Chocolate (CHOC) agar plate, sheep blood agar (SBA) plate, and MacConkey (MAC) agar plate. The large colonies growing on all three plates are gram-negative rods (enterics). These gram-negative rods grow larger, gray, and mucoid on SBA and CHOC agar. Notice the smaller, grayish brown fastidious colonies of *Haemophilus* sp. growing on the CHOC agar (arrow), which are not growing on the SBA or MAC agar.

hemolytic, hemolysis is seen on SBA. Because gram-negative rods produce similar-looking colonies on SBA and CHOC agar, they are better described on MAC agar. MAC agar is also best used to characterize gram-negative rods because **lactose fermenters** can be differentiated from those that do not ferment lactose (**nonlactose fermenters**). Lactose fermenters are easily detected by the color change they produce on the medium; as the pH decreases from lactose fermentation, the organisms produce pink, dark pink, or red colonies (Fig. 8.2A). Colonies of nonlactose fermenters remain clear and colorless (see Fig. 8.2B).

The differentiation of lactose fermentation and nonfermentation is particularly important in screening stool cultures. Most enteric pathogens do not ferment lactose, whereas many bacteria that make up the normal microbiota of the intestines do ferment lactose. Microorganisms grow on culture media in the same proportion or concentration in which they are present in the clinical specimen. Because many specimens are polymicrobial, this feature can be beneficial in identifying different colony types.

The microbiologist must also be aware of factors that can significantly alter the colony morphology of growing microorganisms. Incubation time may differ according to when the specimen is received and processed in the laboratory, and this may affect the typical morphology of a certain isolate. For example, young cultures of *Staphylococcus aureus* may appear smaller and might not show the distinct β -hemolysis that older cultures produce. Therefore it is important that growth on primary culture is observed in no less than 18 hours and no longer than 24 hours of incubation.

Case check 8.2

Certain enteric pathogens, such as ***Escherichia/Citrobacter*-like organisms**, produce dry, pink colonies with a surrounding “halo” of pink, precipitated bile salts (Fig. 8.3), whereas ***Klebsiella/Enterobacter*-like organisms** produce large, mucoid pink colonies that occasionally have cream-colored centers (Fig. 8.4). These characteristics on MAC agar are helpful in presumptive identification. In the Case in Point, dry, dark pink colonies were observed on MAC agar, indicating the presence of a lactose-fermenting, gram-negative rod. Colonies of nonlactose fermenters that were clear and colorless (see Fig. 8.2B) were also recovered from this patient’s sample.

Fig. 8.2 A, Lactose-fermenting, gram-negative rods producing pink colonies on MacConkey (MAC) agar. B, Nonlactose fermenter, gram-negative rods producing colorless colonies on MAC agar.

Fig. 8.3 **A**, Lactose-fermenting *Escherichia/Citrobacter*-like organisms growing on MacConkey (MAC) agar. Notice the dry appearance of the colony and the pink precipitate of bile salts extending beyond the periphery of the colonies. **B**, Close-up of dry, flat *Escherichia/Citrobacter*-like lactose fermenters growing on MAC agar. Compare with Fig. 8.4B.

Fig. 8.4 **A**, *Klebsiella/Enterobacter*-like lactose fermenters growing on MacConkey (MAC) agar. Notice the pink, heaped, mucoid appearance. **B**, Close-up of *Klebsiella/Enterobacter*-like colonies on MAC agar. Notice the mucoid, heaped appearance and the slightly cream-colored center after 48 hours of growth.

Gross colony characteristics used to differentiate and presumptively identify microorganisms

By observing the colony characteristics of the organisms that have been isolated, the microbiologist is able to make an “educated guess” regarding the identification of the isolate. The following descriptions are routinely used to examine colony characteristics. Many of the following colony characteristics may differ among species and strains of the same genus.

Hemolysis

Hemolysis (Greek *hemo*: pertaining to red blood cells [RBCs]; *lysis*: dissolution or break apart) is a reaction caused by enzymatic or toxin activity of bacteria. Hemolysis, observed on SBA seen immediately surrounding or underneath the colony (e.g., α , β , or no hemolysis) with other colony characteristics, is helpful in presumptive identification, particularly of streptococci and enterococci (see Chapter 15). Proper technique

requires the passing of bright light through the bottom of the plate (**transillumination**) to determine whether the organism is hemolytic (Fig. 8.5). Occasionally, the colony must be removed with a loop to visualize the hemolytic pattern. It is important to determine whether true hemolysis is present or whether the discoloration of the medium is the result of growth of the organism on the plate. Organisms that have no lytic effect on the RBCs in SBA are referred to as *nonhemolytic*.

α -Hemolysis

α -Hemolysis is partial lysing of RBCs in an SBA plate around and under the colony that results in a green discoloration of the medium. Examples of organisms that produce α -hemolysis include *Streptococcus pneumoniae* and certain viridans streptococci (see Fig. 8.24 [later] for a comparison of the colony morphology of these organisms).

β -Hemolysis

β -Hemolysis is complete clearing of erythrocytes in SBA around or under the colonies because of the complete lysis of RBCs.

Fig. 8.5 The use of transillumination to determine whether colonies are hemolytic. The technique can be used for MacConkey agar also to see slight color differences in nonlactose fermenters.

Fig. 8.6 Chocolate (CHOC) agar does not display hemolysis because the red cells in the medium have already been lysed. Bacteria that are hemolytic on sheep blood agar usually have a green coloration around the colony on CHOC agar.

Certain organisms, such as group A β -hemolytic streptococci (*Streptococcus pyogenes*), produce a wide, deep, clear zone of β -hemolysis, whereas others, such as group B β -hemolytic streptococci (*Streptococcus agalactiae*) and *Listeria monocytogenes* (a gram-positive rod) produce a narrow, diffuse zone of β -hemolysis close to the colony. These features are helpful hints in the identification of certain bacterial species (see Fig. 8.25 [later] for a comparison of the colony characteristics of group A and group B streptococci). CHOC agar does not display hemolysis because the RBCs in the medium were lysed during media preparation. Organisms that are α -hemolytic or β -hemolytic on SBA usually show a green coloration around the colony on CHOC agar (Fig. 8.6). However, this coloration should not be mistaken for a hemolytic characteristic.

Size

Colonies are described as large, medium, small, or pinpoint. However, a microbiologist rarely measures a colony with

Fig. 8.7 Left, sheep blood agar (SBA) plate: small, white colonies are gram-positive cocci. Right, SBA plate: large, gray, mucoid colonies are enteric gram-negative rods.

Fig. 8.8 Illustration of form or margin to describe colony morphology.

a ruler. Size is generally a visual comparison between genera or species. For example, gram-positive bacteria generally produce smaller colonies than gram-negative bacteria. *Staphylococcus* species are usually larger than *Streptococcus* species. Fig. 8.7 shows colonies of gram-negative rods compared with gram-positive cocci.

Form or margin

The edge of the colonies should be observed and the form, or **margin**, described as **smooth**, **filamentous**, rough, **rhizoid**, or irregular (Fig. 8.8). Colonies of *Bacillus anthracis* on visual

examination are described as “Medusa heads” because of their filamentous appearance. Certain genera such as *Proteus* (especially *Proteus mirabilis*) may swarm on nonselective agar such as SBA or CHOC agar. **Swarming** is a hazy blanket of growth on the surface that extends well beyond the streak lines. Fig. 8.9 shows swarming colonies of *Proteus* spp. Diphtheroids produce colonies that have a dry appearance (Fig. 8.10). Certain yeasts produce colonies that are creamy white with a dull surface and are described as colonies with feet or pedicles, whereas staphylococci produce moist, creamy white to yellowish colonies (see Fig. 8.26 [later] for a comparison of the colony morphology of yeasts and staphylococci).

Fig. 8.9 Swarming colonies of *Proteus* spp. The organism was inoculated in the middle of the sheep blood agar plate (arrow).

Fig. 8.10 “Diphtheroid” colonies with dry appearance and umbonate center growing on sheep blood agar plate.

Elevation

The **elevation** should be determined by tilting the culture plate and looking at the side of the colony (Fig. 8.11). Elevation may be raised, convex, flat, **umbilicate** (depressed center, concave), or **umbonate** (raised or bulging center, convex). *S. pneumoniae* typically produces umbilicate colonies unless the colonies are mucoid because of the presence of a polysaccharide capsule. *S. aureus* typically produces convex colonies. In comparison, β -hemolytic streptococci generally produce flat colonies.

Density

The **density** of the colony can be **transparent**, **translucent**, or **opaque**. To see the differences in the density of colonies, it is useful to look through the colony while using transillumination. Translucent colonies allow some light to pass through the colony, and opaque colonies do not (Fig. 8.12). β -Hemolytic streptococci except group B (*S. agalactiae*) are described as translucent. *S. agalactiae* produces colonies that are semi-opaque, with the organisms concentrated at the center of the colony, sometimes described as a *bull's-eye* colony. Staphylococci and other gram-positive bacteria are usually opaque. Most gram-negative rods also form opaque colonies. *Bordetella pertussis* is described as shiny, similar to a half-pearl, on blood-containing media (see Chapter 18).

Fig. 8.11 Illustration of elevations to describe colony morphology.

Fig. 8.12 Illustration of density to describe colony morphology.

Color

In contrast with pigmentation, *color* is a term used to describe a particular genus in general. Colonies may be white, gray, yellow, or buff. Coagulase-negative staphylococci are white (Fig. 8.13), whereas *Enterococcus* spp. may appear gray. Certain *Micrococcus* spp. and *Neisseria* spp. (nonpathogenic) are yellow or off-white (Fig. 8.14). Diphtheroids are buff. Most gram-negative rods are gray on SBA.

Consistency

Consistency is determined by touching the colony with a sterile loop. Colony consistency may be **brittle** (splinters), **creamy (butyrous)**, dry, or waxy. Occasionally, the entire colony adheres (sticks) to the loop. As examples, *S. aureus* is creamy, whereas certain *Neisseria* spp. are sticky. *Nocardia* spp. produce colonies that are brittle, crumbly, and wrinkled, resembling bread crumbs on a plate. Diphtheroid colonies are usually dry and waxy. Most β -hemolytic streptococci are dry (except for mucoid types), and when pushed by a loop, the whole colony remains intact.

Fig. 8.13 Example of white colonies of coagulase-negative staphylococci on sheep blood agar plate.

Fig. 8.14 Example of the yellow colonies characteristic of certain nonpathogenic *Neisseria* spp. on sheep blood agar plate.

Pigment

Pigment production is an inherent characteristic of a specific organism confined generally to the colony, although some pigments will diffuse through the culture medium. Pigment production is generally enhanced by growing bacteria at room temperature. Examples of organisms that produce pigment include the following:

- *P. aeruginosa*—green, sometimes a metallic sheen (Fig. 8.15)
- *Serratia marcescens*—brick red (Fig. 8.16), especially at room temperature
- *Kluyvera* spp.—blue
- *Chromobacterium violaceum*—purple
- *Prevotella melaninogenica*—brown-black (anaerobic)

Pigment production for these organisms is variable.

Fig. 8.15 **A**, *Pseudomonas aeruginosa* illustrating the metallic sheen and green pigmentation of colonies on sheep blood agar (SBA) plate. **B**, Not all strains of this organism have the same colony appearance. This is a mucoid strain of *P. aeruginosa* on SBA.

Fig. 8.16 Brick-red pigment of *Serratia marcescens* that is evident on MacConkey agar (right). This brick-red pigment should not be confused with lactose fermentation. The pigment is slightly visible on a chocolate agar plate (left). Incubation at room temperature enhances pigmentation.

Fig. 8.17 Large, rough, hemolytic colonies of *Bacillus cereus* on sheep blood agar plate.

Odor

Although certain organisms produce distinctive odors, the microbiologist should never inhale directly from the plate. Odor should be determined when the lid of the culture plate is removed, and the odor dissipates into the surrounding environment. Examples of microorganisms that produce distinctive odors are as follows:

- *S. aureus*—old sock (stocking that has been worn continuously for a few days without washing); this odor is evident when bacteria are growing on mannitol salt agar
- *P. aeruginosa*—fruity or grapelike
- *P. mirabilis*—putrid
- *Haemophilus* spp.—musty basement, “mousy” or “mouse nest” smell
- *Nocardia* spp.—freshly plowed field

Case check 8.3

The Case in Point illustrates the deductive reasoning that occurs during plate reading (colony morphology) of the culture and examination of the direct smear of the clinical specimen. Both techniques have an important role in the presumptive identification required in plate reading. The first step is to examine the direct smear of the specimen for important clues, for example, the presence of white blood cells (an inflammatory process) and specific Gram stain morphology. Gram-positive cocci in pairs and clusters in the direct smear are suggestive of staphylococci (see Chapter 7); it is difficult to distinguish among enteric gram-negative bacilli. The β -hemolytic, white, or off-white, creamy butter-looking, medium colonies on SBA are highly suggestive of *S. aureus* (see Fig. 8.26B). *S. aureus* would be inhibited by MAC agar and would not grow, leaving the other two colony types to identify. The lactose fermenter (pink) on MAC agar with a halo of pink precipitate surrounding the colonies is indicative of *Escherichia/Citrobacter*-like organisms. Of these two, *Escherichia coli* can be β -hemolytic on SBA (see Chapter 19). The nonlactose fermenter is the third type of colony present in the clinical specimen. Both lactose fermenters and nonlactose fermenters are growing on SBA because this medium is noninhibitory but are best differentiated on MAC agar.

Fig. 8.18 Small, “fuzzy-edged,” umbonate center colony of *Eikenella corrodens* on chocolate agar. This organism has the tendency to “pit” the agar.

Colonies with multiple characteristics

In addition to the organisms already mentioned, other bacteria fit in multiple descriptive categories of colony morphology. *Bacillus cereus* forms large, rough, greenish, hemolytic colonies on SBA (Fig. 8.17). *Eikenella corrodens* forms a small, “fuzzy-edged” colony with an umbonate center on SBA or CHOC agar (Fig. 8.18). Roughly one half of the strains will corrode or form pits in the agar.

Growth of microorganisms in liquid media

Important clues to the identification of an organism can also be detected by observing the growth of the organism in liquid media such as thioglycollate. **Streamers** or vines and puffballs are associated with certain species of streptococci (Fig. 8.19). **Turbidity**, which refers to cloudiness of

the medium resulting from growth (and usually gas if the medium contains glucose), is produced by many Enterobacterales (Fig. 8.20). Yeasts and *Pseudomonas* species produce scum at the top and sides of the tube (Figs. 8.21 and 8.22). In addition, yeasts occasionally grow below the surface in the microaerophilic area of the medium (Fig. 8.23).

This chapter discussed the importance of recognizing colony morphology in the initial identification of microorganisms. Fig. 8.24A–B (*S. pneumoniae* and α -hemolytic streptococci),

Fig. 8.24C (*Enterococcus* spp.), Fig. 8.25 (*S. pyogenes* and *S. agalactiae*), and Fig. 8.26 (staphylococci and a yeast) show the differences between various organisms by colony morphology. Microbiologists might become frustrated when microorganisms that produce known characteristic features show atypical results in colony morphology, microscopic morphology, and biochemical reactions. Organisms may exhibit characteristics far different from those previously described for them. The ability to recognize these differences and changes in characteristics makes this discipline a challenge.

Fig. 8.19 A, “Vine” or “streamer” effect exhibited by certain species of streptococci when growing in thioglycollate broth. The effect is more prevalent toward the bottom of the tube. B, “Puffed balls” effect exhibited by certain streptococcal species when growing in thioglycollate.

Fig. 8.21 Production of “scum” by a yeast at the surface of thioglycollate broth.

Fig. 8.20 Turbidity produced by enterics when growing in thioglycollate broth. Notice the gas bubbles at the surface of and in the middle of the medium (arrow).

Fig. 8.22 Illustration of *Pseudomonas* sp. producing surface “scum” at the sides of thioglycollate broth. Occasionally, *Pseudomonas aeruginosa* produces a diffusible green pigment and a metallic sheen at the surface.

Fig. 8.23 Yeast growing in the microaerophilic area of thioglycollate broth.

Differentiation of *Streptococcus pneumoniae*, α -hemolytic viridans streptococci, and *Enterococcus* by colonial morphology

<i>Streptococcus pneumoniae</i>	α -Hemolytic viridans streptococci
Translucent, may resemble a water droplet; umbilicate, or flat with "penny" edge; entire margin, wide and strong zone of α-hemolysis  Umbilicate  "Penny" edge	Translucent, grayer, rough margin, umbonate center   Umbonate center

A

B

C

Fig. 8.24 **A**, Differentiation of *Streptococcus pneumoniae* and α -hemolytic viridans streptococci by colony morphology. **B**, *S. pneumoniae* growing on sheep blood agar (SBA). Notice the strong zone of α -hemolysis, umbilicate center, and wet (mucoid) appearance of the colonies. **C**, *Enterococcus* sp. growing on SBA. It does not have an umbilicate or umbonate center, but it is more heaped and gray-appearing than *S. pneumoniae*. Enterococci form larger colonies and a smooth, darker margin, in contrast with many strains of α -hemolytic streptococci. The green color on the plate is not hemolysis but is a discoloration characteristic of growth.

Fig. 8.25 **A**, Differentiation of *Streptococcus pyogenes* and *Streptococcus agalactiae* by colony morphology. **B**, Tiny colony of *S. pyogenes* exhibiting large, deep zone of β -hemolysis on sheep blood agar (SBA). **C**, Colonies of *S. agalactiae* growing on SBA. This organism produces a larger colony and a smaller, more diffuse zone of hemolysis than *S. pyogenes*. The hemolysis is not evident in this photograph. Compare with **B**. **D**, Colonies of *S. agalactiae* growing on SBA. Through the use of transillumination, the hemolytic pattern is now evident; hemolysis is diffuse, and it remains close to the periphery of the colony. The same colony morphology is produced by *Listeria monocytogenes*, a gram-positive rod. Compare with **B**. *S. pyogenes* (arrow) produces two hemolysins; one is oxygen stable, and the other is oxygen labile. Stabbing the medium with an inoculating loop carries the organism into areas where anaerobic conditions are more prevalent, allowing the enhanced hemolysis (due to the oxygen-labile hemolysin) to be seen.

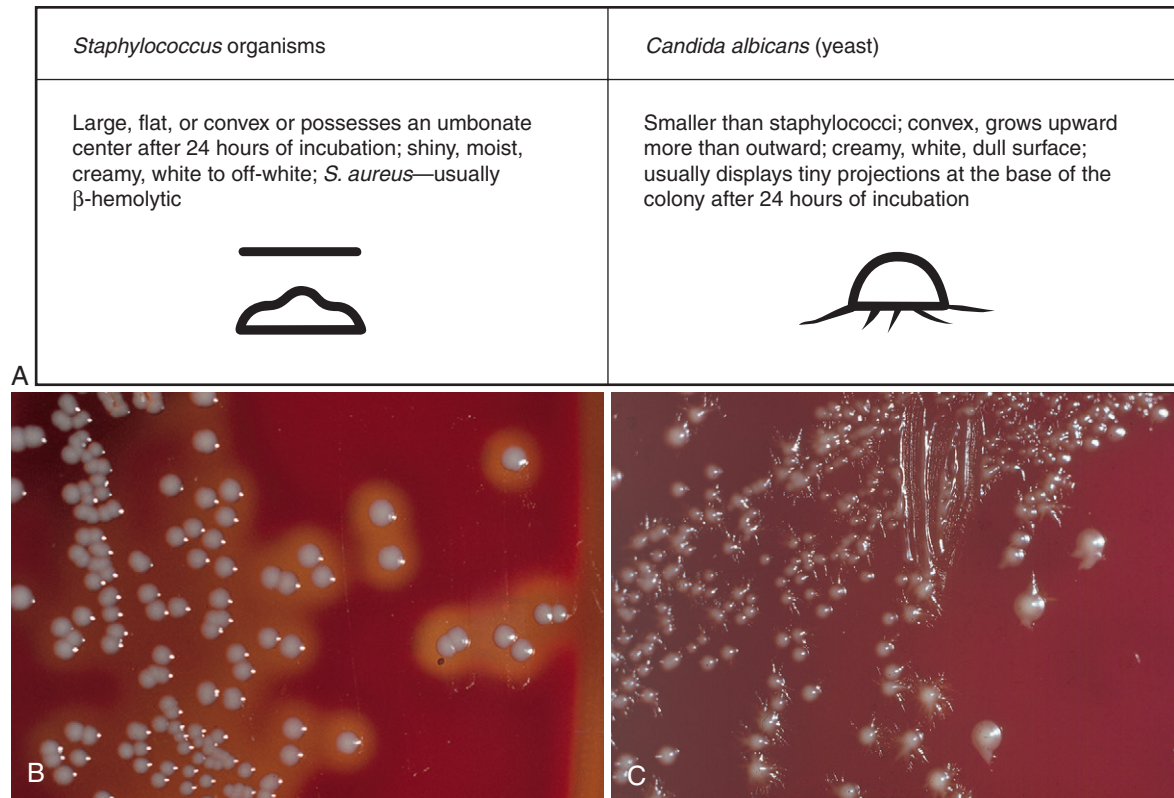

Fig. 8.26 **A**, Differentiation between staphylococci and *Candida albicans* (a yeast) by colony morphology. **B**, Large, white, convex, shiny, moist, β -hemolytic colonies of *Staphylococcus aureus* growing on sheep blood agar (SBA) plate. Most other *Staphylococcus* spp. are nonhemolytic. **C**, “Heaped” or convex, white, dull appearance and butyrous texture of *C. albicans* on SBA. Notice the tiny projections or “feet” at the edge of the colonies.

POINTS TO REMEMBER

- The initial identification process starts with the microscopic morphology on Gram-stained smears and colony morphology of the isolate. Biochemical reactions or molecular biology assays confirm the identification.
- Gram stain of the colony from the culture plate may look different from the direct smear from the specimen. Competition, crowding, and metabolic by-products can alter the Gram stain morphology. For example, in contrast with the direct smear or liquid media, streptococci from the colony may not appear as gram-positive cocci in chains.
- The colony morphology described in this chapter is not infallible. Variations occur quite frequently. The morphologies described are general characteristics for any given organism.

LEARNING ASSESSMENT QUESTIONS

1. What do dark pink colonies on MAC agar indicate? The bacteria are:
 - a. Nonlactose fermenters
 - b. Lactose fermenters
 - c. Gram-positive
 - d. Nonviable
2. In the Case in Point, why are there three colony types that grow on SBA but only two that grow on MAC agar?
3. Which of the following potential pathogens would you suspect if you were to find α -hemolytic colonies from a respiratory sample?
 - a. *Streptococcus pneumoniae*
 - b. *Streptococcus pyogenes*
 - c. Viridans streptococci
 - d. *Haemophilus influenzae*
4. How would you describe the colonies produced on MAC agar by nonlactose fermenting gram-negative bacilli?
5. How would you differentiate β -hemolysis from α -hemolysis?
6. What would you suspect if you noticed “puffballs” growing in broth media?
7. Which genus of bacteria shows “swarming” colonies as a colony characteristic?
 - a. *Klebsiella*
 - b. *Citrobacter*
 - c. *Proteus*
 - d. *Salmonella*
8. A moderate growth of a heaped, dry-appearing, white colony is isolated from a patient suspected of having thrush. The colony has tiny projections extending out along the edge of its margin. Which of the following is a presumptive identification of this organism?
 - a. *Staphylococcus aureus*
 - b. *Staphylococcus epidermidis*
 - c. *Neisseria* spp.
 - d. *Candida albicans*

9. A vaginal culture from a 25-year-old pregnant patient produced colonies on SBA and CHOC agar, but there was no growth on MAC agar. The colonies are described as medium size with small, diffuse zones of β -hemolysis. This type of hemolysis is noticed when a colony is removed with a loop. Which of the following is the suspected identification of this organism?
- Streptococcus pyogenes* (group A)
 - Streptococcus agalactiae* (group B)
 - Streptococcus pneumoniae*
 - Staphylococcus aureus*
10. Which of the following is the reason why hemolysis should not be determined on CHOC agar?
- CHOC is a nonselective agar.
 - Growth factors added on CHOC inhibit hemolysis.
 - Red blood cells in CHOC agar are already lysed.
 - CHOC agar does not support growth of hemolytic organisms.

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Explain the difference between phenotyping and genotyping.
2. Discuss the utilization of lactose by bacteria.
3. Compare the differences between oxidation and fermentation.
4. Explain the different reactions that may be observed in triple sugar iron (TSI) agar.
5. Describe the reactions involved and the products of metabolism tested in each of the following:
 - Ortho-nitrophenyl- β -D-galactopyranoside test
 - Methyl red (MR) and Voges-Proskauer (VP) test
 - Decarboxylase, dihydrolase, and deaminase tests
 - Citrate utilization test
 - Deoxyribonuclease (DNase) test
 - Gelatin liquefaction test
 - Indole test
 - Nitrate and nitrite reduction tests
 - Oxidase test
 - Urease test
 - Lysine iron agar (LIA) test
 - Motility-indole-ornithine (MIO) agar test
 - Sulfide-indole-motility (SIM) agar test
6. Interpret quality control results for biochemical tests used for the identification of gram-negative bacteria.
7. Compare delayed lactose fermenters with nonlactose fermenters.
8. Discuss advantages of multitest systems.
9. Describe the significance of rapid reporting of bacterial identification.
10. Describe how established manual methods have been designed for the rapid identification of isolates.
11. Discuss the evaluation of identification systems.
12. Compare biochemical testing to molecular identification of microorganisms.

KEY TERMS

Asaccharolytic	Moeller decarboxylase base medium
β -galactosidase	Motility-indole-ornithine (MIO) agar
β -galactoside permease	Nitrate reduction test
Chromogenic substrate	Numeric codes
Citrate test	O/F basal medium
Deaminase	Ortho-nitrophenyl- β -D-galactopyranoside (ONPG)
Decarboxylase	Oxidase test
DNase	Oxidation
Fermentation	Phenotype
Fluorogenic substrate	Serotyping
Genotype	Sulfide-indole-motility (SIM) medium
Indole test	Triple sugar iron (TSI) agar
Kligler iron agar (KIA)	Urease test
Lysine iron agar (LIA)	Voges-Proskauer (VP) test
Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry	
Methyl red (MR) test	

Case in point

A 38-year-old male patient with a history of diabetes presented to the emergency department of a small rural hospital with fever and productive cough containing blood of several days' duration. The patient recently returned from Hainan Province, China, where he visited family members. A STAT sputum smear showed a moderate number of neutrophils (less than 10 squamous epithelial cells per high-power field) and a few gram-negative bacilli. A chest computed tomography revealed a patchy opacity in his left lung and multiple low-density lesions in his spleen. A sputum culture yielded growth of normal oral cavity microbiota and moderate growth of an oxidase-positive gram-negative bacillus. The Analytical Profile Index (API) multitest system gave a low percent identification as *Burkholderia pseudomallei*. The microbiology laboratory sent the specimen to a reference laboratory for confirmation.

Issues to consider

After reading the patient's case history, consider:

- What might be significant about this patient's travel to China?
- What are the advantages and disadvantages of multitest systems like the API to identify uncommon gram-negative bacilli?

Historically, the identification of bacteria has been based primarily on colony morphology characterization, microscopic morphology of organisms on Gram-stained smears, and biochemical testing. These methods are based on the **phenotype** of microorganisms, detecting observable or measurable characteristics. Biochemical testing was originally done in test tubes. Although this method was accurate, it required a lot of time to inoculate the multiple tubes of media and required lots of incubator space. Over time, biochemical tests were miniaturized and multitest systems were developed, resulting in

savings of time and space. Later, automated systems were developed. After inoculation, a computerized system records the test results, searches a database, and provides identification of the organism. Automated systems can provide preliminary identification and antimicrobial susceptibility patterns in a few hours. **Serotyping** or serogrouping, another example of phenotypic testing, is sometimes used with biochemical testing for identifying different strains of bacteria within a species. Serotyping uses antibodies to detect specific antigens located on the bacterial surface and is discussed in [Chapter 10](#).

Another phenotypic identification method is based on the analysis of fatty acids in microbial cell walls using gas liquid chromatography. Also, many modern microbiology laboratories now employ matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry. This identification method is based on the characterization of microbial proteins. Some molecular biology assays are based on the **genotype** of the organism and are believed to be more accurate than examining the phenotype. Nucleic acid assays, based on nucleic acid sequences, available for many years now, are highly sensitive, specific, and rapid, providing accurate results in a few hours or less. Genotyping involves characterizing genes and, along with fatty acid analysis and MALDI-TOF mass spectrometry, will be discussed in [Chapter 11](#).

This chapter discusses the principles of conventional biochemical tests used commonly in the identification of gram-negative bacteria. [Box 9.1](#) lists some of these tests. Biochemical testing is becoming less important as clinical laboratories move to faster, more accurate molecular biology methodologies.

Carbohydrate utilization

Among bacteria, there is great diversity in the ability to use carbohydrates; however, determining lactose utilization is the carbohydrate determination test that is most important. Lactose degradation can be used to differentiate bacterial species able to ferment lactose (lactose fermenters) from species that are nonlactose fermenters. Lactose is a disaccharide consisting of glucose and galactose connected by a galactoside bond.

BOX 9.1 Traditional biochemical tests for identification of gram-negative bacteria

- Oxidase test to detect the presence of certain cytochrome C oxidases
- Triple sugar iron (TSI) agar or Kligler iron agar (KIA) to determine glucose and lactose, or sucrose, utilization (sucrose in TSI only) and hydrogen sulfide production
- Methyl red (MR) and Voges-Proskauer (VP) tests to determine end products of glucose fermentation
- Indole test to determine whether indole is formed from tryptophan by tryptophanase
- Urease test to determine hydrolysis of urea
- Simmons' citrate test to determine whether citrate can be used as the sole carbon source
- Carbohydrate fermentation
- Lysine iron agar (LIA) to determine lysine decarboxylase activity
- Sulfide-indole-motility (SIM) or motility-indole-ornithine (MIO) media

Two enzymes are necessary for a bacterium to take up lactose and to cleave it into monosaccharides: **β -galactoside permease** (lactose permease), which serves as a transport enzyme that facilitates entry of the lactose molecule across the bacterial plasma membrane, and **β -galactosidase**, the enzyme that hydrolyzes lactose into glucose and galactose. Lactose fermenters possess both β -galactoside permease and β -galactosidase, and nonlactose fermenters do not possess either enzyme. Some bacterial species lack β -galactoside permease but possess β -galactosidase. These bacterial species, termed *late* or *delayed lactose fermenters*, eventually can cleave the lactose molecule.

After lactose hydrolysis, glucose is available for metabolism primarily through the Embden-Meyerhof-Parnas (EMP) pathway, also referred to as *glycolysis*. Alternatively, bacteria can use the Entner-Doudoroff pathway (Fig. 9.1). See Fig. 1.10 in Chapter 1 for additional description of these pathways. Some bacterial species can only use glucose and are unable to attack the disaccharide lactose. Similarly, bacterial species incapable of fermenting glucose cannot use lactose.

Numerous other carbohydrates—monosaccharides, disaccharides, and polysaccharides—can be used by bacteria. Frequently these carbohydrates are ultimately converted into glucose for use in glycolysis. The polyhydric alcohols (which end in *-ol*), collectively called *sugars*, include adonitol, dulcitol, mannitol, and sorbitol. Some bacteria are not able to use any carbohydrates; instead, they use other organic molecules, such as amino acids, for energy and carbon sources. These organisms are called **asaccharolytic**.

Oxidation-fermentation tests

Bacteria can utilize carbohydrates by **oxidation** (aerobically), **fermentatively** (anaerobically), or both. Determining the oxidation-fermentation (O/F) pattern can be important in the identification of bacteria, particularly gram-negative bacilli. In particular, it is helpful in differentiating members of the order Enterobacterales, those bacteria that are glucose fermenters from the aerobic, nonfermenting pseudomonads.

Carbohydrate fermentation tests determine the ability of a microorganism to ferment a specific carbohydrate incorporated into a basal medium. During **fermentation**, glucose

enters the glycolysis pathway, resulting in the formation of pyruvic acid that can be broken down further into other acids. The end product of carbohydrate fermentation is acid or acid with gas. The pH indicators added to the medium detect acid formation. Some bacteria primarily produce a single acid, such as the streptococci, which are homolactic acid fermenters. Other bacteria produce several different acids and are referred to as *mixed acid fermenters*.

Oxidation also begins with glycolysis; however, the pyruvic acid formed from glycolysis is metabolized further to carbon dioxide (CO_2). Oxidation requires oxygen (aerobic respiration) or another inorganic molecule (anaerobic respiration), such as nitrate (NO_3^-), as a terminal electron acceptor. Greater acidity is produced during fermentation than during oxidation, but less energy is generated.

Characteristically, oxidizers and fastidious fermenters produce either weak or small amounts of acids from carbohydrates. In media that contain large amounts of peptones (1.0%), such as **triple sugar iron (TSI) agar**, whatever acids are produced are neutralized or masked by the alkaline reaction from peptone utilization. To detect small amounts of acids produced, whether fermentatively or oxidatively, Hugh and Leifson developed an **O/F basal medium** (OFBM) that contains the same concentration of carbohydrates (1%) found in TSI medium but a lower concentration of peptones (0.2%). The pH indicator is bromothymol blue. Uninoculated medium is green; in an acid environment, the indicator is yellow; and in an alkaline environment, it is blue (Fig. 9.2).

Table 9.1 shows the differences in reactions among different groups of organisms. The same medium is used for both oxidative and fermentative tests. When O/F tests are performed, two tubes of Hugh-Leifson OFBM are inoculated: one tube is overlaid with sterile mineral oil to create an anaerobic environment (closed), and the other is left aerobic (open), without mineral oil overlay. When acid is produced in both tubes, the isolate is likely a fermenter. Fermentation can

Fig. 9.1 Two pathways for glucose degradation.

Fig. 9.2 Reactions in oxidative fermentative media. The pair of tubes on the *left* is representative of a fermenter: open and oil-overlaid tubes are positive for acid. The pair of tubes in the *center* is representative of an oxidizer/nonfermenter: acid is produced only in the open tube. The pair of tubes on the *right* is representative of a nonoxidizer/nonfermenter: the oil-overlaid tube is unchanged, and the open tube is alkaline from peptone utilization.

Table 9.1 Biochemical reactions characteristic of gram-negative bacilli on TSI, KIA, and OFBM Media

	TSI agar	KIA	Hugh-leifson OFBM
Carbohydrates (concentration)	Glucose (0.1%)	Glucose (0.1%)	Glucose or other carbohydrate being tested (1%)
	Lactose (1%)	Lactose (1%)	
	Sucrose (1%)		
Peptone	2%	2%	0.2%
Fermenter	Acid butt	Acid butt	Open tube: acid
	Acid or alkaline slant	Acid or alkaline slant	Sealed tube: acid
Nonfermenter			
	Oxidizer		
	Alkaline butt	Alkaline butt	Open tube: acid
	Alkaline slant	Alkaline slant	Sealed tube: no acid
Nonoxidizer (asaccharolytic)	Alkaline butt	Alkaline butt	Open tube: no acid
	Alkaline slant	Alkaline slant	Sealed tube: no acid

KIA, Kligler iron agar; OFBM, oxidation-fermentation basal medium; TSI, triple sugar iron.

occur aerobically or anaerobically, if the bacterium is unable to oxidize the carbohydrate. This situation occurs with many streptococci, which derive all energy from fermentation, even in the presence of oxygen. The presence of acid in the closed tube only indicates that the organism is a fermenter and possible obligate anaerobe, whereas the presence of acid in the open tube only indicates an oxidizer. The open tube may or may not show acidity. No acid production in the open tube may indicate that the organism is a nonoxidizer; many nonoxidizers produce an alkaline reaction from peptone utilization.

Triple sugar iron agar

TSI agar and **Kligler iron agar (KIA)** are useful in the presumptive identification of gram-negative enteric bacteria, particularly in screening for intestinal pathogens. The formulas for TSI agar and KIA are identical except that TSI agar contains sucrose in addition to glucose and lactose. Lactose is present in a concentration 10 times that of glucose (1% lactose and 0.1% glucose). In TSI agar, sucrose is also present in a 1% concentration. Ferrous sulfate and sodium thiosulfate are added to detect the production of hydrogen sulfide gas (H_2S). Phenol red is used as the pH indicator, which is yellow below a pH of 6.8. Uninoculated medium is red because the pH is buffered at 7.4. Both TSI agar and KIA are useful in detecting the ability of bacteria to ferment carbohydrates (glucose and lactose in KIA and glucose, lactose, or sucrose in TSI agar); to produce gas from the fermentation of sugars; and to detect the production of H_2S .

Both TSI agar and KIA are poured on a slant. The slant portion is aerobic; the butt, or deep portion, is anaerobic. To

inoculate TSI agar or KIA, the laboratory scientist should pick a well-isolated colony with an inoculating needle and stab the butt almost all the way to the bottom of the tube. The laboratory scientist removes the needle and then uses a back-and-forth motion across the surface of the slant. The cap is replaced loosely to allow oxygen to enter the tube, and the medium is incubated in a non- CO_2 incubator for 18 to 24 hours. The reaction patterns are written with the slant results first, followed by the butt reaction, separated by a slash (slant reaction/butt reaction). It is important that the reactions be read within 18 to 24 hours; otherwise, erroneous results are possible.

Reactions on triple sugar iron agar or kligler iron agar

1. *No fermentation: alkaline slant/alkaline butt (K/K) or alkaline slant/no change (K/NC).* Although unable to ferment either lactose or glucose, these organisms can degrade the peptones present in the medium aerobically or anaerobically, resulting in the production of alkaline by-products in the slant or deep, respectively, changing the indicator to a deep red color. These reactions are typical of organisms that are not members of the order Enterobacterales.
2. *Glucose fermentation only, no lactose (or sucrose in TSI) fermentation: alkaline slant/acid butt (K/A).* TSI agar and KIA contain glucose in a 0.1% concentration. The acid produced from this concentration of glucose is enough to change the indicator to yellow initially throughout the medium. However, after about 12 hours, the glucose is consumed, and bacteria on the slant utilize the peptones aerobically, producing an alkaline reaction, which changes the indicator to a deep red color. Fermentation of glucose (anaerobic) in the butt produces larger amounts of acid, overcoming the alkaline effects of peptone degradation; therefore the butt remains acidic (yellow). Reading the results after less than 12 hours of incubation (acid/acid) gives the false appearance of an organism capable of fermenting glucose and lactose (or sucrose in the case of TSI agar). For this reason, TSI agar or KIA must be incubated for 18 to 24 hours.
3. *Lactose and/or sucrose fermentation: acid/acid (A/A).* Glucose fermenters attack the simple sugar glucose first and then lactose or sucrose. The acid production from the fermentation of the additional sugar is sufficient to keep both the slant and the butt acidic (yellow) when examined at the end of 18 to 24 hours of incubation. If the medium is incubated beyond 24 hours, however, it is possible that the lactose or sucrose could be consumed, and an alkaline slant could be formed from peptone utilization. It is important that the TSI agar and KIA tests are not read after 24 hours of incubation.
4. *H_2S production: alkaline slant/acid butt, H_2S in butt (K/A, H_2S) or acid slant/acid butt, H_2S in butt (A/A H_2S).* H_2S production is a two-step process. In the first step, H_2S is formed from sodium thiosulfate. Because H_2S is a colorless gas, the indicator, ferrous sulfate, is necessary to visually detect its production. In some cases, the butt of the tube is completely black, obscuring the yellow color from carbohydrate fermentation. Because H_2S production requires an acid environment, even if the yellow color cannot be seen, it is safe to assume glucose fermentation.

- a. Bacterium (acid environment) + sodium thiosulfate → H₂S gas
- b. H₂S + ferric ions → ferrous sulfide (black precipitate)
5. Gas production (aerogenic) or no gas production (nonaerogenic). The production of gas results in the formation of bubbles or splitting of the medium in the butt or complete displacement of the medium from the bottom of the tube. Fig. 9.3 illustrates the reactions on TSI agar.

Ortho-nitrophenyl-β-D-galactopyranoside test

Organisms that are delayed lactose fermenters appear initially as nonfermenting colonies on primary isolation media. When placed on TSI agar or KIA slants, these species produce similar results after 18 to 24 hours of incubation. The **ortho-nitrophenyl-β-D-galactopyranoside** (ONPG) and the *p*-nitrophenyl-β-D-galactopyranoside (PNPG) tests determine whether the organism is a delayed lactose fermenter (one that lacks the enzyme β-galactoside permease but possesses β-galactosidase) or a true nonlactose fermenter. Structurally, ONPG is similar to lactose, but ONPG is more readily transported through the bacterial plasma membrane and does not require β-galactoside permease. β-Galactosidase hydrolyzes ONPG, a colorless compound, into galactose and *o*-nitrophenol, a yellow compound. ONPG remains colorless if the organism is a nonlactose fermenter (Fig. 9.4).

The test can be performed by making a heavy suspension of bacteria in sterile saline and adding commercially prepared ONPG disks or tablets. The suspension is incubated at 35° C, and positive results can generally be seen within 6 hours. β-Galactosidase is an inducible enzyme. The gene is expressed only if lactose or a similar substrate is present; therefore bacteria should be taken from lactose-containing media for testing. Bacteria producing a yellow pigment should not be tested because of the risk of a false-positive result.

Glucose metabolism and its metabolic products

Glucose metabolized via the Embden-Meyerhof pathway produces several intermediate by-products, including pyruvic acid. Further degradation of pyruvic acid can produce mixed acids as end products. However, enterics take two separate pathways: the mixed acid fermentation pathway or the butylene glycol pathway. The **methyl red (MR) test** and the **Voges-Proskauer (VP) test** detect the end products of glucose fermentation. Each test detects products from a different pathway.

Methyl red test

Bacteria are incubated in a broth medium containing glucose. Most commercial methyl red–Voges-Proskauer (MRVP) media are a modification of Clark and Lubs medium. The broth should be incubated 3 to 5 days at 35° C. After incubation, approximately one half of the broth is transferred to a clean, dry tube for the VP test. If glucose is metabolized by the mixed acid fermentation pathway, stable acid end products are produced, which results in a low pH. A red color develops after

Fig. 9.3 Triple sugar iron agar reactions. Left to right, A/A gas; A/A H₂S; K/A; K/A H₂S; K/K.

Fig. 9.4 Ortho-nitrophenyl-β-D-galactopyranoside (ONPG) test. (Courtesy American Society for Clinical Laboratory Science, Education and Research Fund, Inc., 1982.)

addition of the pH indicator MR (Fig. 9.5). MR-negative cultures remain yellow after addition of the pH indicator (pH 6.0).

Glucose → Pyruvic acid → Mixed acid fermentation (pH 4.4)

Red color with methyl red indicator

Voges-Proskauer test

In some bacteria, acids formed during fermentation can be metabolized further to 2,3-butanediol through the intermediate acetoin. After incubation, α-naphthol is added first as a catalyst or color intensifier. Next, 40% potassium hydroxide (KOH) or sodium hydroxide (NaOH) is added, and the tube is gently shaken to increase oxygenation. Under these

Fig. 9.5 **A**, Methyl red–Voges-Proskauer (MRVP) test is inoculated and incubated overnight. It is then split equally into two parts: one part for the methyl red (MR) test, the other for the Voges-Proskauer (VP) test. **B**, MR test. **C**, VP test. W, Weak positive. (Courtesy American Society for Clinical Laboratory Science, Education and Research Fund, Inc., 1982.)

conditions, acetoin is oxidized to diacetyl. Diacetyl in the presence of KOH and α -naphthol forms a red complex. The pH remains relatively neutral. Fig. 9.5 illustrates the MRVP test. Bacteria tend to be either MR or VP positive, but not both. Some bacteria are negative for both tests.

Amino acid utilization

Decarboxylase and dihydrolase tests

Many bacteria can use amino acids as energy and carbon sources. **Decarboxylase** tests determine whether the bacterial species possess enzymes capable of decarboxylating (removing the carboxyl group, COOH) specific amino acids in the test medium. Lysine and ornithine are two amino acids

commonly used to test for decarboxylase activity. The products of decarboxylation are amine or diamine molecules and CO₂, with resulting alkalinity. Degradation of the amino acids and their specific end products are shown in the following reaction:

Degradation of amino acids and their specific end products

Lysine (amino acid) $\rightarrow$ Lysine decarboxylase $\rightarrow$

Cadaverine (amine) + CO₂

Ornithine $\rightarrow$ Ornithine decarboxylase $\rightarrow$ Putrescine

Arginine $\rightarrow$ Arginine dihydrolase $\rightarrow$ Citrulline $\rightarrow$

Ornithine $\rightarrow$ Putrescine

Lysine is decarboxylated by the enzyme lysine decarboxylase to cadaverine, a diamine, and CO₂. Ornithine is cleaved by ornithine decarboxylase to putrescine, a diamine, and CO₂. Both cadaverine and putrescine are stable in anaerobic conditions. Arginine can be decarboxylated in a two-step process. In the first step, arginine undergoes decarboxylation by arginine decarboxylase to form agmatine and CO₂. Then agmatine

is metabolized further to putrescine and urea. If the bacteria also produce urease, the urea is degraded to ammonia (NH_3) and CO_2 . Arginine also can be degraded by arginine dihydrolase forming citrulline, ammonia, and inorganic phosphate. In the next step, citrulline undergoes phosphorolytic cleavage to yield ornithine. If the bacteria also possess ornithine decarboxylase, ornithine is converted to putrescine.

The test to detect decarboxylation uses **Moeller decarboxylase base medium**. The broth contains glucose; peptones; two pH indicators, bromocresol purple and cresol red; and the specific amino acid at a concentration of 1%. The medium has an initial pH of 6.0. Having glucose in the medium is important because decarboxylases are inducible enzymes produced in an acid pH. The uninoculated medium is purple; metabolism of the small amount of glucose decreases the pH to about 5.5, turning the medium yellow. For decarboxylation to take place, two conditions must be met: an acid pH and an anaerobic environment. A control tube containing only the base medium without the amino acid is inoculated to determine the viability of the organism. The control tube also determines whether sufficient acid is produced. Both tubes are inoculated with the test organism; overlaid with a layer of sterile mineral oil, which creates anaerobic conditions; and then incubated at 35° C.

During the first few hours of incubation, organisms attack the glucose first, changing the pH to acid. If the organism produces the specific decarboxylase and the amino acid in the medium is attacked, release of the amine products causes an alkaline pH shift, resulting in a purple (positive result) color in the medium. If the organism does not possess the specific decarboxylase, the medium remains yellow (negative result). The control tube should remain yellow. Results can usually be recorded in 24 hours; however, bacteria with weak decarboxylase activity may take 4 days to be positive. Modifications of the decarboxylase test to detect other biochemical reactions are also used. Examples of these include the MIO and LIA tests (Fig. 9.6).

Fig. 9.6 Lysine iron agar reactions. *Left to right*, K/K (positive decarboxylation without H₂S), K/A H₂S (negative decarboxylation with H₂S), K/K H₂S (positive decarboxylation with H₂S), R/Y (negative decarboxylation, positive deamination without H₂S).

Deaminase test

Amino acids can be metabolized by **deaminases** that remove an amine (NH_2) group. The phenylalanine deaminase (PAD) test determines whether an organism possesses the enzyme that deaminates phenylalanine to phenylpyruvic acid. The test medium is an agar slant containing a 0.2% concentration of phenylalanine. The surface of the slant is inoculated with a bacterial colony. After incubation, addition of a 10% ferric chloride (FeCl_3) reagent results in a green color if phenylpyruvic acid is present. This test is helpful in initial differentiation of *Proteus*, *Morganella*, and *Providencia* organisms, which are positive, from the rest of the Enterobacterales (Fig. 9.7).

Deamination of Phenylalanine

Phenylalanine → Phenylalanine deaminase →
Phenylpyruvic acid + (FeCl_3) green

Miscellaneous tests

Citrate utilization

The **citrate test** determines whether an organism can use sodium citrate as a sole carbon source. Simmons' citrate medium is frequently used for this test. In addition to citrate, the test medium contains ammonium salts as the sole nitrogen source. Bacteria able to use citrate will use the ammonium salts, releasing ammonia. The alkaline pH that results from ammonium salts utilization changes the pH indicator (bromothymol blue) in the medium from green to blue. It is important to use a light inoculum because dead organisms can be a source of carbon, producing a false-positive reaction (Fig. 9.8). Christensen's citrate medium is an alternative test medium. This medium incorporates phenol red (as the pH indicator) and organic nitrogen. At an alkaline pH, the indicator turns from yellow to pink.

Fig. 9.8 Citrate utilization test. *Left*, Uninoculated. *Center*, Positive result. *Right*, Negative result.

Fig. 9.9 Indole broth. (Courtesy American Society for Clinical Laboratory Science, Education and Research Fund, Inc., 1982.)

Deoxyribonuclease (DNase) production

Deoxyribonucleic acid (DNA) is a polynucleotide composed of repeating purine and pyrimidine mononucleotide monomeric units. Most bacterial deoxyribonucleases (**DNases**) are endonucleases cleaving internal phosphodiester bonds, resulting in smaller subunits. Extracellular DNase can be produced by numerous bacteria, such as *Staphylococcus aureus* and *Serratia marcescens*. DNase test medium usually contains 0.2% DNA. A heavy inoculum of bacteria is streaked onto the surface of the medium in a straight line; several organisms can be tested at once. The plate is incubated at 35° C for 18 to 24 hours, and then 1 N HCl is added to the surface of the plate. Unhydrolyzed DNA is insoluble in HCl and forms a precipitate. Oligonucleotides formed from the action of DNase dissolve in the acid, forming a clear zone (halo) around the inoculum, a positive result. An alternate formulation incorporates methyl green into the medium. Methyl green complexes with DNA forming a green color. If the DNA is broken down by bacterial DNases, DNA can no longer bind methyl green, and the green color fades. A clear zone around the bacteria indicates a positive result.

Indole production

Indole is one of the degradation products of the amino acid tryptophan. Organisms that possess the enzyme tryptophanase are capable of deaminating tryptophan with the formation of the intermediate degradation products of indole, pyruvic acid, and ammonia. Bacteria are inoculated into tryptophan or peptone broth. Most commercial peptone broth contains enough tryptophan for a positive reaction; tryptophan can be added to a final concentration of 1%. After inoculation, the broth should be incubated at 35° C for 48 hours. After incubation, one of two methods can be used to detect indole. In the Ehrlich **indole test**, the indole is extracted from the broth culture by the addition of 1 mL of xylene. After the xylene is added, the tube is shaken well. After waiting a few

minutes for the xylene to rise to the top, 0.5 mL of Ehrlich's reagent, containing *p*-dimethylaminobenzaldehyde (PDAB), is added. If indole is present, a red color develops after the addition of PDAB (Fig. 9.9). Alternatively, Kovac's reagent, which also contains PDAB, can be used. This method does not use a xylene extraction. Approximately five drops of Kovac's reagent are added directly to the broth culture. The tube is shaken, and if indole is present, a red color develops. The Ehrlich method is more sensitive than Kovac's reagent and is preferred with nonfermentative bacteria. If indole-nitrate (trypticase nitrate) medium is used, the indole test can be performed from the same broth culture as a nitrate test. Before adding any reagents, the broth is divided in half, one aliquot for the indole test and the other for the nitrate test. A rapid indole test is available. Isolated bacterial colonies are smeared onto filter paper that has been moistened with *p*-dimethylaminocinnamaldehyde. The formation of a blue-green color within 2 minutes is a positive reaction indicating the presence of indole in the bacterial colony.

Lysine iron agar slant

The **lysine iron agar (LIA)** test is a tubed agar slant containing the amino acid lysine, glucose, ferric ammonium citrate, and sodium thiosulfate. The pH indicator is bromocresol purple. LIA is used primarily to determine whether bacteria decarboxylate or deaminate lysine (see Fig. 9.6). H₂S production is also detected in this medium. LIA is inoculated in the same manner as a TSI agar slant. LIA is most useful in conjunction with TSI in screening stool specimens for the presence of enteric pathogens, differentiating *Salmonella* spp. (lysine-positive) from *Citrobacter* spp. (lysine-negative). Decarboxylation only occurs anaerobically; the presence of a dark purple butt is positive for lysine decarboxylation. The production of H₂S can mask the purple color in the butt of the tube. Because H₂S production in LIA occurs only in an alkaline environment, a black precipitate indicating H₂S is also a positive result for decarboxylation. LIA is also useful in differentiating *Proteus*,

Morganella, and *Providencia* spp. from most other members of the order Enterobacterales. This group of enterics deaminates (attacks the NH_2 group instead of the carboxyl group) amino acids. In the LIA slant, deamination of lysine turns the original light purple color slant to a plum or reddish-purple color; the butt turns yellow because of glucose fermentation.

Case check 9.1

In the Case in Point at the beginning of the chapter, the patient's history and laboratory culture results implied an infection caused by *B. pseudomallei*. This bacterium causes the disease melioidosis, which is uncommon in the United States. It is most prevalent in tropical regions such as Southeast Asia. Nonfermentative gram-negative bacilli tend to be more difficult to identify biochemically because they have fewer positive reactions. In addition, uncommon isolates tend to be more difficult to identify in commercial identification systems partly because of an insufficient number of known samples analyzed for the system's database.

Motility

Motility can be determined by microscopic examination of bacteria or by observing growth in a semi-solid medium. Motility test media have agar concentrations of 0.4% or less to allow for the free spread of microorganisms. A single stab is made into the center of the tubed medium. Best results are obtained if the stab is made as straight as possible. After incubation, movement away from the stab line or a hazy appearance throughout the medium indicates a motile organism. Incubation temperature is important. Some bacteria are motile only at room temperature, but this temperature may not be optimal for growth. It is suggested that two motility tubes be inoculated, one incubated at room temperature and the other at 35° C. Comparing inoculated with uninoculated tubes may help in interpreting results.

Motility-indole-ornithine agar

Motility-indole-ornithine (MIO) agar is a semi-solid agar medium used to detect motility and indole and ornithine decarboxylase production. MIO is useful in differentiating *Klebsiella* spp. from *Enterobacter* and *Serratia* spp. The medium is inoculated by making a straight stab down the center of the medium with an inoculating needle. Motility is shown by a clouding of the medium or spreading growth from the line of inoculation. Ornithine decarboxylation is indicated by a purple color throughout the medium. Because MIO is a semi-solid medium, it does not have to be overlaid with mineral oil to provide anaerobic conditions. Indole production is detected by the addition of Kovac's reagent; a pink to red color is formed in the reagent area if the test result is positive. Ornithine decarboxylase and motility should be read first before the addition of Kovac's reagent.

Nitrate and nitrite reduction

The **nitrate reduction test** determines whether an organism has the ability to reduce nitrate to nitrite and reduce nitrite further to nitrogen gas (N_2). The organism is inoculated into

a nutrient broth containing a nitrogen source. After 24 hours of incubation, *N,N*-dimethyl- α -naphthylamine and sulfanilic acid are added. A red color indicates the presence of nitrite.

Nitrate reduction test reaction

Nutrient broth with 0.1% potassium nitrate $\rightarrow$

Nitrate reductase $\rightarrow$ Nitrite $\rightarrow$ Sulfanilic acid +

N,N – Dimethyl – α – naphthylamine $\rightarrow$ Diazo red dye

If no color develops, this may indicate that nitrate has not been reduced or that nitrate has been reduced further to N_2 , nitric oxide (NO), or nitrous oxide (N_2O), which the reagents will not detect. Adding a small amount of zinc dust will help determine whether the test has produced a true-negative result or whether the lack of color production was caused by reduction beyond nitrite. Zinc dust reduces nitrate to nitrite. Therefore development of a red color after the addition of zinc confirms a true-negative test result. Alternatively, a small glass tube, called a *Durham tube*, can be inserted into the broth upside down when the medium is aliquoted into test tubes. During incubation, if nitrogen gas is produced, it will be trapped in the inverted Durham tube.

Oxidase

The **oxidase test** determines the presence of the cytochrome oxidase system that oxidizes reduced cytochrome with molecular oxygen. The oxidase test is helpful in differentiating between Enterobacterales, which are oxidase-negative (except for *Plesiomonas*), and the pseudomonads, which are oxidase-positive. The oxidase test is also useful in identifying *Neisseria* spp., which are oxidase positive. A modified oxidase test is used to distinguish *Staphylococcus* from *Micrococcus*. Several methods for performing an oxidase test are available. Kovac's oxidase test uses a 0.5% or 1% aqueous solution of tetramethyl-*p*-phenylenediamine dihydrochloride. A drop of the reagent is added to filter paper, and a wooden applicator stick is used to rub a colony onto the moistened filter paper. The development of a lavender color within 10 to 15 seconds is a positive reaction. *p*-Aminodimethylaniline oxalate is less sensitive than tetramethyl-*p*-phenylenediamine dihydrochloride, but it is cheaper and more stable. Commercial forms of oxidase reagent are available in glass ampules and on filter paper disks. An oxidase test should not be performed on bacteria grown on plates with dyes, like eosin-methylene blue, because this can result in false-positive results.

Sulfide-indole-motility agar

Sulfide-indole-motility (SIM) medium is a semi-solid agar helpful in differentiating gram-negative bacteria in the order Enterobacterales. An inoculating needle is used to make a straight stab down the center of the medium. Cloudiness spreading from the inoculation line is positive for motility. The production of H_2S is indicated by a black precipitate, and a pink to red color after the addition of Kovac's reagent is positive for indole.

Urease

The **urease test** determines whether a microorganism can hydrolyze urea, releasing enough ammonia to produce a

color change by a pH indicator. Urease hydrolyzes urea to form ammonia, water, and CO₂. Different formulations of urea agar are available, but Christensen's urea agar is generally preferred. The surface of the agar slant is inoculated but not stabbed. The medium contains phenol red as the pH indicator. The resulting alkaline pH from hydrolysis of urea is indicated by a bright pink color (Fig. 9.10).

Case check 9.2

Identification confirmation for uncommonly isolated nonfermentative gram-negative bacilli is often based on genomic nucleic acid sequencing or MALDI-TOF mass spectrometry. The rural hospital in this case requested confirmation from a regional medical center. The identification was confirmed by genomic sequencing.

Manual multitest systems

Principles of identification

Microbial identification methods fall into one of five categories or a combination thereof: (1) pH-based reactions, (2) enzyme-based reactions, (3) utilization of carbon sources, (4) visual detection of bacterial growth, or (5) molecular assays based on the characterization of molecules including volatile or nonvolatile fatty acids, nucleic acids, and proteins. Immunoassays, discussed in Chapter 10, rely on antibodies to detect microbial antigens. Most of the assays require microbial growth, but detection of nucleic acids does not (Table 9.2). The molecular assays are discussed in Chapter 11.

Identification of bacteria and yeasts can be facilitated by using automated or packaged kit systems by which organisms are identified with computer-assisted databases or computer-derived **numeric codes**. These numeric codes are generated based on the metabolic profiles of each organism.

Fig. 9.10 Urease test. Left, Negative result. Right, Positive result.

Each metabolic reaction, or phenotype, is recorded as plus (+) for positive reactions and minus (–) for negative reactions. These plus-minus sequences are cataloged as binary numbers and stored in a computer database. Binary codes are computer-converted to code profile numbers that represent the identifying phenotype of specific organisms. After metabolic profiles have been converted to numbers, a percent probability of correct identification is assigned based on the comparison of the unknown profile with known profiles within the database. As more organisms are included in the database, the genus and species designations and probabilities become more precise. With the frequent name changes that occur, it is sometimes difficult to maintain the current taxonomy in a database. All commercial suppliers of multicomponent biochemical test systems provide users with one or more of the following: a computer with profile number database, a computer-derived code book, access to a website, or access to a telephone inquiry center to facilitate matching profile numbers with species.

Analytical profile index

The Analytical Profile Index (API; bioMérieux, Durham, NC) was released in 1970. The system for identification of gram-negative fermentative bacteria (the order Enterobacterales) is called the *API 20E*. This system has a series of 20 cupules attached to a plastic strip. Inside the cupules are lyophilized, pH-based substrates. A bacterial suspension made in saline is used to rehydrate the reagents in the cupules. The principles of the tests are the same or similar to the principles of tests performed in test tubes. Some of the cupules, such as those for amino acid deaminases and dehydrolase, require a mineral

Table 9.2 Methodologies for microbial identification		
System	Growth needed?	Comment
pH-based	Yes	Carbohydrate and amino acid utilization (e.g., API)
Enzyme profile	No	Rapid results (2 to 4 hours) based on the presence of preformed enzymes (e.g., MicroScan rapid panels)
Carbon source utilization	Yes	Color change based on transfer of electrons to colorless indicator, producing a colored compound (e.g., Biolog)
Volatile or nonvolatile compound detection	Yes	Fatty acids detected by chromatographic assays (e.g., MIDI)
Visual detection of growth	Yes	Growth determined by presence of turbidity (e.g., MicroScan)
MALDI-TOF mass spectrometry	Yes	Protein patterns determined by mass spectrophotometry (e.g., Bruker)
Target DNA	No	Sequence target DNA and compare to public database or nucleic amplification and probe detection (e.g., Gen-Probe)
API, Analytical Profile Index; MALDI-TOF, matrix-assisted laser desorption/ionization–time-of-flight.		

oil overlay to achieve anaerobiosis. The strip is incubated 18 to 24 hours at 35° C, and reagents are added to some of the cupules. The last test used to determine the profile number is the oxidase test, which is not part of the API strip. Results are recorded, and a 7-digit code profile number is determined.

After determining the code profile number, a database provided by the manufacturer is consulted, providing the most probable identification. If the identification is in question, nitrate reduction and motility are supplemental tests that can be used to obtain an additional digit for the profile number. The API system has been a standard product in many clinical microbiology laboratories and has remained unchanged. Accuracy for commonly isolated members of the order Enterobacterales, such as *Escherichia coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis*, has been reported to be 87.7% at 24 hours of incubation. For less commonly isolated Enterobacterales, the accuracy is 78.7% at 24 hours. bioMérieux markets many multitest API systems, including systems for gram-positive cocci, nonfermentive gram-negative bacilli (20NE), yeasts (API 20C), and a rapid system for identification of Enterobacterales in 4 hours (RapID 20E).

Other multitest systems include Crystal E/NF (BD Diagnostic Systems, Sparks, MD), RapID NF Plus (Thermo Fisher Scientific, Waltham, MA), Microbact Biochemical Identification (Thermo Fisher Scientific), Enterotube II (BD Diagnostic Systems), and Micro-ID (Thermo Fisher Scientific). Biolog (Hayward, CA) markets the Gen III MicroLog M manually read system.

Rapid and automated identification systems

Until the late 1970s, microbiologists relied on the growth and isolation of bacteria in broth and agar media. Once bacteria are cultured in vitro, their biochemical or metabolic characteristics can be used for identification. Isolation of the infectious agent from clinical samples typically requires 24 to 48 hours. Identification protocols often require another 24 hours of incubation in the presence of specific biochemical substrates. Rapid diagnosis of infectious disease remains a challenge for the clinical microbiology laboratory. The rapid and accurate reporting of results should positively affect patient outcomes by quick initiation of appropriate antimicrobial therapy. This allows the clinical microbiology laboratory to have a proactive, rather than retrospective, effect on patient management.

Rapid reporting also becomes increasingly important considering today's diagnostic challenges. Newly emerging pathogens, recognition of old pathogens in different clinical settings, world travel, increases in healthcare-associated infections, and the prevalence of multidrug-resistant organisms all contribute to the need for the design and development of new identification capabilities. Some of the major concepts and applications of rapid methods and automation currently available for the identification of clinically significant microorganisms are listed in the following sections. Although not exhaustive, the principles of most rapid identification technologies found in the clinical microbiology laboratory have been included. Other rapid identification methods are discussed in [Chapters 10](#) and [11](#). Specific identification methods are discussed in greater detail in chapters in association with specific organism descriptions.

The term *rapid*

Direct microscopic examination of body fluids provides results within 15 to 30 minutes; these results are often valuable in patient management. For example, Gram stain results from a cerebrospinal fluid specimen along with blood and spinal fluid chemistry (glucose and protein) and hematology (complete blood count and differential) may be critical in establishing the cause of infectious meningitis. However, direct microscopy generally has a low sensitivity. [Chapter 7](#) discusses the microscopic examination of clinical samples.

For decades, microbiologists relied on the ability of an organism to ferment sugars, degrade amino acids, and produce unique end products for identification purposes. Diagnosis of an infectious disease has been a complex, laborious, and frequently slow process. In the late 1950s and 1960s, traditional biochemical tests became miniaturized. Smaller test tubes and molded plastic vessels were introduced. These changes made testing more convenient but did not improve turnaround times in reporting results. In the 1970s, microbiologists began to rely on computerized databases so numerous results could be considered simultaneously, and the most statistically probable result could be regarded as the identification of the unknown organism. This improved the reliability of results but still did not improve reporting turnaround times. In the mid- to late 1970s, semiautomated instruments for identification and susceptibility testing gradually appeared. In many laboratory settings, these instruments shortened turnaround times, yielded greater accuracy, and improved productivity.

The phrase *rapid method* encompasses a wide variety of procedures and techniques and has been loosely applied to any procedure affording results faster than the conventional method. Rapid methods exist for microscopy, biochemical identification, antigen detection, and antibody detection. *Rapid* is a relative term used to describe time, and it depends on the procedures being compared. For example, a 3-hour enzyme immunoassay method to detect *Clostridioides difficile* toxin is rapid compared with a 48-hour cell culture cytotoxicity assay. The fluorescence quenching-based oxygen sensor detection of *Mycobacterium tuberculosis* within 2 weeks with the BACTEC 9000 MB (BD Diagnostic Systems) is rapid compared with the 6 weeks required to grow the organism on agar slants.

Microscopic procedures using common stains and fluorescent-labeled antibody to detect specific organisms are rapid methods; so are some conventional procedures used for initial differentiation or presumptive identification of certain groups of organisms. These procedures have been modified to provide immediate results that may lead to presumptive identification. Rapid identification of clinical isolates by biochemical reactions often involves commercially packaged identification kits or fully automated instruments. These manufactured kits are usually miniaturized test systems that employ chromogenic or fluorogenic substrates to assess preformed enzymes. **Chromogenic substrates** are colorless; when cleaved by a microbial enzyme, a colored compound is produced. **Fluorogenic substrates** are nonfluorescent until cleaved by microbial enzymes. Reaction endpoints may be reached after 2 to 6 hours of incubation, although some may require overnight incubation. The capabilities of these kits and systems vary widely. Certain systems may still require manual reading

by the laboratory scientist, whereas others may use mechanized reading through spectrophotometry, numeric coding, and computerized databases. Some of these instruments also incubate, read, and interpret the enzymatic test results.

Rapid biochemical tests performed on isolated colonies

Table 9.3 summarizes the principles, modes of action, and applications of certain established manual procedures for quick presumptive differentiation among groups of organisms or presumptive identification to bacterial species. Often more than one test must be performed for a presumptive identification. These tests may also provide direction about additional tests needed for definitive identification. Further discussion of these and other rapid biochemical methods is included in subsequent chapters as they apply to identification of specific organisms.

Identification systems relying on carbohydrate utilization or chromogenic substrates

Rapid tests for detection of end products resulting from carbohydrate metabolism or enzymatic tests using chromogenic

substrates produce reaction endpoints in minutes to hours. Plastic cupules, reaction chambers, or filter paper strips contain desiccated or dehydrated reagents or substrates. In general, a suspension of bacterial cells or a loopful of an isolated colony is added to the system or rubbed off to a reaction area. A positive reaction is measured by enzymatic activity and color change.

Multitest kits using conventional carbohydrate metabolism take advantage of one test inoculum distributed to multiple reaction sites to yield more than one result. To obtain more rapid results, conventional methods have been modified by decreasing the test substrate medium volume and increasing the concentration of bacteria in the inoculum. Methods based on enzyme substrates have certain advantages over conventional methods. Because enzymatic methods involve preformed enzymes, they do not require multiplication of the organism (growth independent). Endpoints are reached in minutes to a few hours. The tests are very sensitive for the presence of the enzyme, although not always specific for genus and species identification; however, sensitivity depends on the concentration and stability of the substrate, the enzyme, and the age of the inoculum. Several rapid modifications of conventional methods for bacterial and yeast identification are listed in Table 9.4. Thermo Fisher Scientific markets a series of RapID panels that can provide identification in about 4 hours (Fig. 9.11).

Table 9.3 Rapid biochemical tests performed on isolated colonies

Test	Bacterial enzyme	Mode of action	Applications
Spot indole	Tryptophanase	Organism from blood agar or any tryptophan-containing medium is placed on a swab, and reagent is added; hydrolysis of tryptophan to indole is indicated by production of blue to blue-green color on addition of DMAC	Positive reaction aids in identification of <i>Escherichia coli</i> , <i>Proteus vulgaris</i> ; aids in identification of anaerobes
ONPG	β -Galactosidase	Ester linkage of ortho-nitrophenyl moieties to various carbohydrates; hydrolysis results in release of yellow ortho-nitrophenol	Determines lactose fermentation (yellow color) in slow lactose fermenters; differentiates <i>Neisseria lactamica</i> from pathogenic <i>Neisseria</i> spp.
Oxidase	Cytochrome-c oxidase	Blue compound is produced when tetramethyl- <i>p</i> -phenylenediamine reacts with cytochrome c	Differentiation of nonfermenters; aids in identification of <i>Neisseria</i> , <i>Aeromonas</i> , <i>Vibrio</i> , and <i>Campylobacter</i> spp.
Catalase	Catalase	Breakdown of hydrogen peroxide into oxygen and water, resulting in rapid production of bubbles	Differentiation of staphylococci from streptococci and of <i>Listeria</i> spp. from streptococci
Bile solubility		Autocatalyzes colony in the presence of the surfactant sodium deoxycholate (bile salt)	Presumptive identification of <i>Streptococcus pneumoniae</i> in sputum, blood, and CSF cultures
PYR	PYR	Hydrolysis of amide substrate with formation of free β -naphthylamide, which combines with DMAC to form a bright red color	Identification of group A streptococci; differentiates <i>Enterococcus</i> from group D streptococci
Rapid urease	Urease	Rapid hydrolysis of urea by urease releases ammonia; alkalinity causes phenol red indicator to change from yellow to red	Screening test for <i>Cryptococcus</i> , <i>Proteus</i> , and <i>Klebsiella</i> spp. and <i>Yersinia enterocolitica</i>
Rapid hippurate hydrolysis	Hippuricase	Enzymatic hydrolysis of hippurate visualized by addition of ninhydrin (triketohydrindene)	Positive reaction aids in identification of <i>Streptococcus agalactiae</i> , <i>Campylobacter jejuni</i> , and <i>Listeria</i> spp.
MUG	β -Glucuronidase	Hydrolysis of substrate to fluorescent compound MUG, which fluoresces blue under long-wave UV light	Presumptive identification of <i>E. coli</i> and <i>Streptococcus anginosus</i> group; enterohemorrhagic <i>E. coli</i> is negative
LAP	LAP	LAP hydrolyzes substrate to leucine and α -naphthylamine, which reacts with DMAC to form a red color	Presumptive identification of catalase-negative, gram-positive cocci

CSF, Cerebrospinal fluid; DMAC, *p*-dimethylaminocinnamaldehyde; LAP, leucine aminopeptidase; MUG, 4-methylumbelliferyl- β -D-glucuronide; ONPG, ortho-nitrophenyl- β -D-galactopyranoside; PYR, pyrrolidonyl aminopeptidase; UV, ultraviolet.

Table 9.4 Commercially available manual and automated systems for microbial identification

Name	Manufacturer	Principle	Organisms identified
Manual			
API	bioMérieux ^a	Carbohydrate utilization/ chromogenic substrate	Enterobacterales, other GN bacilli, <i>Staphylococcus</i> spp., <i>Streptococcus</i> spp., <i>Enterococcus</i> spp., <i>Neisseria</i> spp., GP bacilli, yeasts, anaerobes
Crystal E/NF	BD Diagnostic Systems ^b	Carbohydrate utilization/ chromogenic substrate	Enterobacterales, other GN bacilli, <i>Neisseria</i> spp., <i>Haemophilus</i> spp., GP cocci, GP bacilli
MicroLog	Biolog ^c	Carbohydrate utilization	GP organisms, GN organisms, yeasts, anaerobes
Gonocheck	TCS Bioscience ^d	Chromogenic substrate	<i>Neisseria/Moraxella</i> spp.
Micro-ID (RapID)	Thermo Fisher Scientific ^e	Carbohydrate utilization/ chromogenic substrate	Enterobacterales, other GN bacilli, <i>Neisseria</i> spp., <i>Haemophilus</i> spp., streptococci, enterococci, yeasts, anaerobes, UTI, GP bacilli
MicroScan (TouchScan)	Beckman Coulter ^f	Carbohydrate utilization/ chromogenic substrate	GP organisms, GN organisms, UTI, <i>Haemophilus</i> spp., <i>Neisseria</i> spp.
Oxi-Ferm II	BD Diagnostic Systems	Carbohydrate utilization	Nonfermenter GN bacteria
Automated			
BD Phoenix	BD Diagnostic Systems	Carbohydrate utilization/ chromogenic substrate/fluorogenic substrate	Enterobacterales, other GN bacilli, GP
MicroScan (Autoscan, WalkAway)	Beckman Coulter	Carbohydrate utilization/ chromogenic substrate/fluorogenic substrate	Enterobacterales, other GN bacilli, <i>Neisseria</i> spp., <i>Haemophilus</i> spp., streptococci, enterococci, staphylococci, GP bacilli, yeasts, anaerobes
OmniLog	Biolog	Carbohydrate utilization/ tetrazolium violet reduction	GN organisms, GP organisms, anaerobes
Sensititre (TREK)	ThermoFisher Scientific	Carbohydrate utilization/ chromogenic substrate	GN organisms, GP organisms, anaerobes
Sherlock Microbial Identification System	MIDI ^g	Fatty acid analysis of microbial cells	GN organisms, GP organisms, <i>Mycobacterium</i> spp., yeasts
Vitek 2	bioMérieux	Carbohydrate utilization/ chromogenic substrate	Enterobacterales, other GN bacilli, <i>Neisseria</i> spp., <i>Haemophilus</i> spp., streptococci, enterococci, staphylococci, GP bacilli, yeasts, anaerobes

Automated identification systems

Several automated identification systems are currently available; most of these systems use turbidity, colorimetry, or fluorescence technology. These systems have a variety of capacities depending on laboratory workflow. Fully automated systems incubate and read the reactions, and computer software interprets the results and provides the identification. An advantage of automated systems includes an interface to laboratory information systems, leading to decreased turn-around times for reporting results. Other advantages include statistical prediction of correct identification, increased data

acquisition and epidemiologic analysis, and automated standardization of identification profiles that can reduce analytical errors. If these systems are used in conjunction with automated susceptibility testing, these data may be linked to the pharmacy for patient management applications. A key application of automated systems is the direct testing of positive blood cultures. Theoretically, early reporting of results can shorten the length of hospital stay, augment therapeutic management of appropriate antimicrobial agents, and thus decrease hospital costs.

Whether using manual multitest (as discussed previously) or automated systems, laboratories use an incubated “purity” plate of the inoculum to accompany the identification procedure. Because many specimens are polymicrobial, a purity plate ensures that the inoculum was pure and was not mixed with another microorganism that would produce erroneous results. With the threat of biological terrorism, automated systems address the rapid, accurate identification of biothreat level A organisms. Many of these organisms, such as *Bacillus anthracis*, *Francisella tularensis*, and *Yersinia pestis*, are rarely seen in clinical microbiology laboratories. Manufacturers of identification systems have responded by including updated data on biothreat level A organisms in their identification databases. However, the identification of some rarely isolated pathogenic bacteria can be inaccurate.

MicroScan systems

The MicroScan System (Beckman Coulter, Brea, CA) consists of plastic standard-size, 96-well microtiter trays in which 32 reagent substrates are included for the identification of bacteria and yeasts. Two systems are available: autoSCAN and WalkAway. Some trays, called *combo trays*, include broth microdilutions of various antimicrobial agents for performing susceptibility tests along with biochemical tests for identification. Some panels are designed for overnight incubation, while the rapid panels provide preliminary results in as soon as 2 hours and final results in 18 hours. MicroScan panels contain dehydrated substrates allowing for room temperature storage and a long shelf life. The wells are inoculated with a heavy suspension of the organism to be tested and incubated at 35° C. Conventional panels are incubated for a minimum of 16 hours to about 20 hours. The autoSCAN system reads standard panels in an automated tray reader that detects bacterial growth or color changes by differences in light transmission. As with other automated systems, identification of the organism is accomplished digitally by collating the readings and matching them to the system’s software database for final identification. The MicroScan WalkAway is fully automated with capabilities to incubate multiple panels (40 or 96 depending on the system), add reagents automatically to conventional panels when required, read and interpret panel results, and print results, all without operator intervention (Fig. 9.12).

In addition to the conventional MicroScan panels, rapid fluorescence panels are available for use in the WalkAway instrument. The rapid panels use fluorescent-labeled compounds to test for preformed enzymes; these panels require only about 2.5 hours for bacterial identification, and the antimicrobial susceptibility is determined in about 7 hours. Fluorometric reactions detect changes in pH because of carbohydrate fermentation. The resultant acid production causes a decrease in pH and a decrease in fluorescence.

Fig. 9.12 WalkAway 96 plus System featuring the test platform and automated data management system. (Courtesy Siemens Healthcare Diagnostics, Tarrytown, NY.)

Studies have indicated that directly inoculating positive blood cultures into MicroScan Combo plates using the WalkAway 96 instrument can yield rapid and accurate results for bacterial identification and antimicrobial susceptibility testing. A study of 1070 positive blood cultures reported that 96.5% of isolates (1033/1070) were identified correctly by the direct method. The antimicrobial susceptibility testing revealed an overall categorical agreement of 92.86% between the direct method and conventional testing.

TREK diagnostic system

The TREK Diagnostic System (Thermo Fisher Scientific) offers two automated systems: the Sensititre Autoreader and the fully automated Sensititre ARIS2X identification system. The Sensititre system uses fluorescence technology to detect bacterial growth and enzyme activity. The system comprises 32 biochemical tests, including selected classic biochemical media reformulated to yield a fluorescent signal. The biochemical test medium, along with an appropriate fluorescent indicator, is dried into the individual wells of the Sensititre plate. Each biochemical reaction is repeated three times in the 96-well plates; each plate is designed to test three separate organisms. All tests are read on the Sensititre Autoreader for the presence or absence of fluorescence. Results are available as soon as 5 hours, although incubation can be extended to overnight if needed. The results are transmitted to a computer for analysis and identification. Plates for antimicrobial susceptibility testing only are also available.

Vitek 2 system

The Vitek 2 system (bioMérieux Inc.) was first introduced in the 1980s. A suspension of the organism is prepared in saline and incorporated into a card. The card is then placed in the reader-incubator module of the instrument, where it is optically scanned and read periodically. The computer software collates the readings and matches them to the database for

final identification. The reader/incubator can accommodate 15, 30, 60, or 120 cards depending on the system. Numerous cards are available for gram-positive cocci, coryneforms, fermentative gram-negative bacilli, nonfermentative gram-negative bacilli, *Haemophilus*, *Neisseria*, and yeasts.

Compared with 16S ribosomal RNA (rRNA) sequencing, the Vitek 2 identified correctly 43 of 50 (86%) anaerobic bacteria to the species level and 47 (94%) to the genus level. In a larger study of 1020 bacterial isolates and 5 fungi, 92.59% (949/1025) isolate identifications matched by the Vitek 2 and the Vitek MALDI-TOF mass spectrometry. Discordant results were identified by 16S rRNA sequencing. Authors reported no errors at the genus level for MALDI-TOF mass spectrometry, whereas the Vitek 2 made 6 (0.58%) errors. Bacteria in the study included typical clinical isolates such as *Pseudomonas* spp., *Acinetobacter* spp., Enterobacterales, and some slow-growing bacteria (*Eikenella corrodens*, *Listeria monocytogenes*, *Haemophilus influenzae*, and others). Another study of over 4000 microorganisms that included gram-positive bacteria, gram-negative bacteria, and yeast found an overall excellent identification agreement between MALDI-TOF mass spectrometry and the Vitek 2.

BD phoenix automated microbiology system

The BD Phoenix Automated Microbiology System (BD Diagnostic Systems) was released in the United States in 2004. Once the 136-well combination panels are inoculated, it is a totally hands-off system that can hold 100 panels: 99 samples and 1 control. Panels are read every 20 minutes for up to 16 hours. Results are generally available in 2 to 12 hours for bacteria and 4 to 15 hours for yeasts. Various colorimetric and fluorometric indicators are used for identification, and a colorimetric redox indicator is used for antimicrobial susceptibility testing. In a study in which 618 isolates were identified by the Phoenix system and MALDI-TOF mass spectrometry, the concordance (agreement) rate was 95.9% at the genus level for nonfermentative gram-negative bacilli and 81.6% at the species level. The concordance rate for gram-positive bacteria was 100% at the genus level and 86.6% at the species level.

Biolog OmniLog ID system

The fully automated Biolog OmniLog ID System is based on the organism's ability to utilize 71 carbon sources and sensitivity to 27 chemical substances. One 96-well plate is used for each organism. The reduction of tetrazolium violet is used as the indicator system. The Biolog database is one of the largest, with more than 2900 species or taxa. Panels are available for aerobic and anaerobic gram-positive and gram-negative bacteria and yeasts. The Gen III OmniLog ID System is a semiautomated system. The Biolog system is not approved for human in vitro testing but is widely used in agricultural and veterinary microbiology laboratories.

Evaluation of identification systems

Most rapid and automated procedures are designed to provide results with greater speed and precision than traditional methods. Many multitest and automated systems are highly accurate and can provide results in 2 to 4 hours, particularly with the Enterobacterales. These systems typically display

lower accuracy with coagulase-negative staphylococci; non-fermentative gram-negative bacilli; and slower-growing, more fastidious bacteria, such as anaerobes.

Whether greater efficiency and productivity are achieved with multitest systems depends largely on the laboratory and the institution or institutions that it supports. Manual and automated systems should be evaluated onsite before changing or augmenting current protocols. The best studies are prospective, side-by-side comparisons of the current in-house or reference procedure with the new system for accuracy, cost-effectiveness, and effect on workflow. Most microbiologists consider 16S rRNA sequencing as the reference method in comparison studies. Automated systems often provide decreased sensitivity and specificity for the identification of biochemically inert bacteria and some fastidious organisms compared with other bacteria. Therefore supplemental and differential media and conventional biochemicals still must be available to support the identification of these organisms. Whether it is a multitest manual method or an automated system, regular updating of the database is critical for accurate identification and correct names of the microorganisms.

POINTS TO REMEMBER

- Phenotyping, serotyping, and genotyping all have important uses in the identification of bacteria.
- Molecular biology assays, such as nucleic acid amplification tests and MALDI-TOF mass spectrometry, provide accurate identification more rapidly than conventional biochemical testing.
- Bacteria can utilize carbohydrates oxidatively, fermentatively, or not at all.
- TSI agar and KIA are useful in determining the ability of bacteria to utilize certain carbohydrates and to produce H_2S .
- The MR and VP tests are used to determine the end products of glucose fermentation.
- Decarboxylase, dihydrolases, and deaminases are enzymes used by bacteria to metabolize amino acids.
- Numerous tests, such as citrate, DNase, indole, nitrate reduction, oxidase, and urease, are important in the identification of gram-negative bacteria.
- Manual multitest systems have improved the identification of bacteria by simplifying inoculation of many different biochemical tests and producing numeric codes that can be compared with numbers in a database.
- Rapid tests often use chromogenic or fluorogenic substrates to assay for preformed bacterial enzymes.
- Automated microbial identification systems offer accurate, rapid identifications with less hands-on time by laboratory scientists.

LEARNING ASSESSMENT QUESTIONS

1. Which of the following tests detects the production of mixed acids from glucose because of subsequent metabolism of pyruvate?
 - a. Methyl red test
 - b. Voges-Proskauer test
 - c. Citrate test
 - d. Indole test

2. The metabolism of glucose to pyruvate by members of the order Enterobacterales is via the Embden-Meyerhof-Parnas pathway. The subsequent metabolism of pyruvate shows this reaction: glucose → pyruvate → acetylmethylcarbinol (acetoin) → 2,3-butanediol. This reaction is the basis for the:
 - a. Oxidase reaction
 - b. Methyl Red test
 - c. Indole test
 - d. Voges-Proskauer test
3. A gram-negative bacillus that produces an acid slant and acid butt on triple sugar iron agar can ferment which of the following carbohydrates?
 - a. Glucose only
 - b. Glucose and lactose or sucrose or both
 - c. Lactose only
 - d. Lactose and sucrose, but not glucose
4. Why is an oil overlay used when testing carbohydrate utilization?
 - a. Minimizes the risk of airborne contamination
 - b. Provides a nutrient source
 - c. Creates an anaerobic environment
 - d. Enhances activity of the pH indicator
5. Tryptophan broth is inoculated and incubated 24 hours. After incubation, Kovac's reagent is added. A red color develops at the surface of the broth. Which product of metabolism was formed?
 - a. Mixed acids
 - b. H₂S
 - c. Phenylpyruvate
 - d. Indole
6. In the citrate utilization test, a positive result is determined by:
 - a. Increase in pH from peptone metabolism
 - b. Increase in pH from urease activity
 - c. Decrease in pH from citrate utilization
 - d. Decrease in pH from nitrate reduction
7. Lysine deaminase:
 - a. Cleaves a carboxy group from lysine
 - b. Cleaves an amino group from lysine
 - c. Adds an amino group to lysine
 - d. Adds a carboxy group to lysine
8. While performing quality assurance on a new lot of triple sugar iron slants, the control organisms gave the following results: *E. coli*, yellow/yellow with gas, *Salmonella* Typhimurium, red/yellow with a black precipitate in the butt. Which of the following statements is true?
 - a. The yellow slant indicates glucose fermentation only.
 - b. The yellow butt of *E. coli* and *Salmonella* indicates galactose fermentation.
 - c. The black precipitate indicates citrate utilization.
 - d. The red slant of *Salmonella* indicates nonlactose fermentation and nonsucrose fermentation.
9. A bacterium is isolated that produces clear colonies on MacConkey agar after 18 hours of incubation. Laboratory testing reveals a positive ONPG, a positive methyl red, and a negative Voges-Proskauer. What do these results indicate about the bacterium's ability to utilize carbohydrates?
 - a. Sucrose fermentation is positive
 - b. Can oxidize lactose but cannot ferment it
 - c. Delayed lactose fermentation
 - d. Uses glucose anaerobically
10. Indole-positive bacteria:
 - a. Produce tryptophanase
 - b. Deaminate lysine
 - c. Decarboxylate tryptophane
 - d. Decarboxylate ornithine
11. How do bacteria that are able to ferment lactose rapidly differ from bacteria that are delayed lactose fermenters?
12. After 24-hour incubation of a nitrate broth with visible growth, *N,N*-dimethyl- α -naphthylamine and sulfanilic acid are added. No color change is noted. What are two possible explanations concerning the reduction of nitrate? What should you do next to determine which explanation is correct?

Bibliography, 226

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Define *antigen*.
2. Compare the structure and function of immunoglobulin G and immunoglobulin M.
3. Discuss the importance of acute and convalescent antibody titers.
4. Interpret significant antibody titer results.
5. Compare polyclonal and monoclonal antibodies.
6. Explain the causes of false-negative and false-positive immunologic test results.
7. Justify screening women who are considering pregnancy for rubella antigens.
8. Rationalize the absorption of biotin from clinical specimens before performing a biotin/streptavidin immunoassay.
9. Justify using an enzyme immunoassay instead of an indirect fluorescent assay to detect antibodies
10. Recognize the significance of serologic tests in the following situations:
 - Population studies
 - Immune status testing
 - Congenital infections
 - Infections beyond the newborn period
11. Describe the principles and applications of each of the following immunologic methods:
 - Precipitation assays
 - Agglutination assays
 - Neutralization assays
 - Immunofluorescent assays
 - Enzyme immunoassays
 - Complement fixation (CF)
 - Western blot
 - Dot blot
12. Compare direct agglutination, passive agglutination, and reverse passive agglutination.
13. Describe the clinical applications of antibody detection for the following diseases:
 - Syphilis
 - *Streptococcus pyogenes* infection
 - Infectious mononucleosis
 - Viral hepatitis
 - Human immunodeficiency virus (HIV) infection
 - Fungal infections

14. Describe the current clinical applications of direct antigen detection methods in each of the following infectious diseases:

- *Streptococcus pyogenes* infection
- Respiratory tract viral infections
- Bacterial meningitis
- Giardiasis and cryptosporidiosis
- HIV infection
- Infections in immunocompromised patients

KEY TERMS

Acute phase	Hybridoma
Anamnestic immune response	Immune complex
Antibody titer	Immunodiffusion
Antigens	Immunogen
Avidity	Indirect agglutination
Biotin-streptavidin systems	Indirect fluorescent antibody (IFA)
Chemiluminescent immunoassay (CLIA)	Indirect sandwich immunoassay
Coagglutination	Monoclonal antibody
Competitive immunoassays	Polyclonal antibody
Complement fixation (CF)	Postzone
Conjugate	Precipitation
Convalescent phase	Prozone
Cytopathic effect (CPE)	Radial immunodiffusion
Direct fluorescent antibody (DFA)	Radioimmunoassay (RIA)
Direct sandwich immunoassay	Reagin antibodies
Double immunodiffusion	Reverse passive agglutination
Epitopes	Rheumatoid factor (RF)
False-negative	Seroconversion
False-positive	Serology
Fluorochrome	Specificity
Heterophile antibodies	Zeta potential
	Zone of equivalence

Case in point

A previously healthy, 33-year-old male patient presents to his physician with an unintended 10-lb weight loss over a 3-month period, intermittent diarrhea for several months, and a fever of unknown cause. A complete blood count revealed a slightly elevated white blood cell (WBC) count. The WBC differential was 72% neutrophils, 15% monocytes, 10% lymphocytes, and 3% eosinophils. Based on these findings and the clinical presentation, the physician ordered a blood test for antibodies directed against human immunodeficiency virus (HIV). The result of the screening test was reactive.

Issues to consider

After reading the patient's case history, consider:

- The importance of the patient's case history and laboratory results
- The significance of the blood test for HIV
- What additional test should be performed next
- The role of cultures and direct antigen detection in the diagnosis of infectious diseases

The phenomenon of bacterial agglutination in human sera was discovered in 1896 and was quickly recognized as a powerful tool by bacteriologists. Not only could sera be used to identify and differentiate bacteria (serotyping), but also the sera from infected patients could be tested for the ability to agglutinate a known microorganism. The reaction of patients' sera with bacteria was indicative of prior exposure to the organism and of the level of immune response and protection against the infectious agent. The proteins in human sera causing bacterial agglutination, called *antibodies*, form because of infection by microorganisms.

Serology (literally "the study of serum") is the study of antibodies and their reaction with **antigens**, molecules that bind specifically to antibodies or T-cell receptors, in the diagnosis of infectious diseases. These tests originally referred to the use of serum or plasma, but now several body specimens including cerebrospinal fluid (CSF) and urine are used. Fluorescent immunoassays can also be performed on tissue. Immunologic assays based on the principles of antibody-antigen reactions are also used to detect and quantify analytes, such as serum proteins, hormones, and drugs, in clinical chemistry and forensic science. Immunoassays are used in several point-of-care tests and home test kits.

Perhaps the greatest advantage of serologic testing is that it is an excellent means for detecting infectious agents that are either difficult or impossible to culture. Certain infectious agents, such as viruses or some sexually transmitted bacteria, are difficult to culture, usually because of either their specific growth requirements or previous antimicrobial therapy that decreases the number of viable organisms. Many fungi and mycobacteria also take an extremely long time to grow. In addition, many organisms are not grown because of significant risk to laboratory scientists. Serologic tests can be used not only under these conditions but also for prognostic information and in the monitoring of therapy, such as with chronic hepatitis.

As powerful as immunologic tests are, using serologic procedures in diagnosis has disadvantages. The most significant problem is that to measure the host immune response to an organism, 10 to 14 days must pass after the onset of an infection. In some cases (e.g., HIV, hepatitis B virus [HBV], and hepatitis C virus [HCV]), weeks to months must pass before antibody levels are detectable. Immunocompromised patients can have an antibody response that is either diminished or nonexistent, impairing the ability to use any serologic procedure. Also, the antibody being detected may have been produced against another organism, and a **false-positive** test is observed.

The discovery that immune hemolysis could be mediated by anti-erythrocyte antibodies in the presence of complement and could be titrated added a new approach to the diagnosis of infectious diseases. The serum of patients could be examined for the presence of antibodies that do not agglutinate or precipitate their respective antigens, but activate, or fix, complement. This serologic method, known as **complement fixation** (CF), is a very sensitive method for detecting antibodies to their corresponding antigens.

The first practical laboratory tests for detecting newly discovered infectious agents are still generally based on serology. The types of tests available continue to increase, allowing the diagnosis of many new infectious diseases. For example, acquired immunodeficiency syndrome (AIDS), viral hepatitis,

and Lyme disease are most frequently diagnosed in the laboratory with serologic tests. These three diseases all are caused by infectious agents that are difficult to cultivate in laboratories. Although currently available serologic tests for these and other agents are not perfect, improvements have resulted from advances in preparation of antibodies and antigens of high purity. A wide variety of high-quality commercial kits are available. Immunologic tests also are used to detect antigens that are detectable earlier than antibodies; however, they are not available for as many organisms as the classic antibody detection tests. This chapter discusses the aspects of using immunologic assays to diagnose infectious disease by detecting either antibodies or antigens in patient samples.

Antibodies in serologic testing

Antigens

Antigens are relatively high-molecular-weight substances, usually proteins or polysaccharides (less commonly, lipids or nucleic acids either alone or complexed to proteins or polysaccharides), that combine specifically with antibody molecules. Antigens that are recognized as foreign substances by a host are said to be *immunogenic*, capable of eliciting an immune response. Often, the terms *antigen* and **immunogen** are used interchangeably; the former term refers to the antibody-binding properties of the molecule, whereas the latter refers to the antibody-eliciting property of the molecule.

The typical immune response to a large complex antigen, such as a bacterium or a virus, results in the stimulation of many different lymphocytes with differing **specificity** to the available antigenic determinants (**epitopes**). Chapter 2 provides an explanation of antibody formation. Most natural antigens are extremely large. Therefore the response generated to these molecules is polyclonal, resulting in a mixture of antibodies recognizing different epitopes with different binding affinities. A **polyclonal antibody** is composed of a mixture of antibody molecules derived from multiple cells against multiple epitopes found on an antigen or directed against different antigens altogether. For instance, when an animal or person is exposed to any bacterium, different antibody molecules are made to each of the numerous epitopes found on different antigens on the bacterium.

Microorganisms contain a wide array of molecules capable of eliciting an immune response in the host. Immunogenic substances may be structural or nonstructural components of the microorganism. For example, many pathogenic bacteria have polysaccharide capsules that coat the organism. Because these capsules are located on the cell surface, they are often the first antigenic determinants recognized by the host. Additional structural antigenic components are the bacterial cell wall, membrane proteins, and pili proteins. Nonstructural antigens include bacterial enzymes and toxins that may be found within the cell or are released into host tissues. Because many bacterial components are “hidden” within the cell, antibody responses to some of them may not develop until the cell has been degraded by the host’s innate immunity (e.g., phagocytic cells, complement). A single infecting bacterial species typically stimulates the production of numerous antibodies with different specificities.

Acute and convalescent antibody titers

In serologic assays, a patient’s serum is tested for antibodies reactive to specific antigens taken from an infectious agent. If the antibodies are present, this indicates an infection at some point in the patient’s life. It is possible to semi-quantitate the amount of antibody by making serial twofold (doubling) dilutions of the serum, producing progressively lower concentrations of antibody (e.g., 1:2, 1:4). A standard amount of antigen from an infectious agent is mixed with each antibody dilution, and the antibody-antigen reactions are detected in some manner. A positive result is reported as an **antibody titer**, which is the reciprocal of the highest dilution of serum showing reactivity. However, this type of serial dilution method is not very precise, and the difference of only one tube dilution is not considered significant in determining the presence of a recent infection. Antibody tests for a wide variety of infectious agents are commercially available (Table 10.1). Antigen-antibody (**immune complex**) detection methods, along with specific diagnostic applications, are discussed later in this chapter.

An individual’s first exposure to an infectious agent primarily results in the production of immunoglobulin M (IgM). Subsequent exposure to the same antigen elicits a secondary

Table 10.1 Examples of commercially available serologic tests for diagnosis of infectious disease

Type of infection	Serologic test methods available
Bacterial	
<i>Bordetella pertussis</i>	EIA
<i>Borrelia burgdorferi</i>	EIA, IFA, WB
<i>Helicobacter pylori</i>	EIA
<i>Legionella pneumophila</i>	EIA, ICT, IFA
<i>Mycoplasma pneumoniae</i>	EIA, ICT, IFA
<i>Streptococcus pyogenes</i>	NT, QN
<i>Treponema pallidum</i>	IFA, EIA, flocculation
Fungal	
<i>Histoplasma capsulatum</i>	CF, ID, LA
Parasitic	
<i>Toxoplasma gondii</i>	EIA, IFA, LA
Viral	
Cytomegalovirus	EIA, IFA
Epstein-Barr virus	CIA, EIA, ICT, IFA, LA, WB
Hepatitis viruses A, B, and C	CIA, EIA
Herpes simplex virus	EIA, ICT, IFA, WB
HIV types 1 and 2	CIA, EIA, ICT, IFA, WB
Influenza viruses A and B	CF, EIA, HAI
RSV	CF, EIA, IFA
Rubella virus	EIA, HAI, LA, WB

CF, Complement fixation; CIA, chemiluminescence; EIA, enzyme immunoassay; HA, hemagglutination; HAI, hemagglutination inhibition; HIV, human immunodeficiency virus; ICT, immunochromatographic test; ID, immunodiffusion; IFA, indirect fluorescent antibody; LA, latex agglutination; NT, neutralization; QN, qualitative nephelometry; RSV, respiratory syncytial virus; WB, Western blot.

Fig. 10.1 Primary and secondary antibody responses.

or **anamnesic immune response**, which is characterized by a rapid increase in immunoglobulin G (IgG) associated with higher levels, a prolonged elevation, and a more gradual decline (Fig. 10.1). IgM antibody synthesis plays a minor role in a secondary immune response. Serologic tests that are designed to detect IgG and IgM antibodies separately take advantage of the differences in IgM production between a primary and a secondary immune response. A positive test result for IgM antibody is considered suggestive of a primary, current, or very recent infection, whereas the presence of IgG antibody alone suggests a previous infection or exposure. Interpretation of high IgM antibody titers must be made cautiously. In some infectious diseases, high IgM levels can persist beyond the acute state. Alternatively, a negative IgM titer does not exclude an infection because it can sometimes take several weeks after onset of an infection before IgM will be detectable.

Similarly, the presence of significant levels of IgM antibody (with or without IgG) in a newborn suggests an in utero infection. IgM can be synthesized by the fetus and cannot cross the placenta from mother to fetus, whereas the presence of IgG antibody only in the newborn is indicative of passive maternal transfer of IgG across the placenta, not in utero infection.

Several methods are available for removal or inactivation of serum IgG, allowing for preferential detection of IgM. One of the most common methods for physical removal of IgG uses commercially available miniature ion-exchange chromatography columns to trap IgM, while allowing IgG to be washed through with a buffer solution. The IgM antibody is collected by elution from the column with a lower pH buffer. Another method of removing IgG from whole serum uses adsorption to protein A found in the cell wall of staphylococci. Protein A binds most subclasses of human IgG, facilitating their removal. Also, anti-human IgG inactivates or removes (requires precipitation and centrifugation) IgG for IgM-specific assays. This method has the additional advantage of removing **rheumatoid factor** (RF) that would bind to the IgG–anti-IgG complexes. RF is present in cases of rheumatoid arthritis and some other autoimmune disorders.

It is sometimes practice to test a single serum specimen for IgG antibody to attempt to diagnose a recent or past infection. In many cases, the presence of IgG antibody is difficult or impossible to interpret; it may represent a past infection,

either clinically apparent or subclinical (without overt symptoms). A relatively high titer of IgG does not necessarily indicate a recent infection. Antibody levels vary based on host genetics, age, comorbidities, and the immunogenicity of the infectious agent. A high antibody titer simply means that the host is a high responder to that specific antigen and has a history of infection. However, in certain cases, such as infections that are rare (e.g., rabies) or have been present for a relatively long time (chronic) when symptoms first appear (e.g., AIDS), the presence of IgG antibody in a single serum specimen might be diagnostic. IgG and IgM testing should be performed concurrently.

Unless a serologic test is designed to measure IgM-specific and IgG-specific antibody in a single serum specimen, serologic diagnosis of an infectious disease requires measurement of total antibody concentration in both **acute-phase** and **convalescent-phase** serum specimens. Specific IgG antibody is usually not detected in serum collected during the acute phase of the illness (within 1 week of manifestation of symptoms). A significant increase in IgG detected during the convalescent (recovery) phase, usually 2 weeks later, is diagnostic for infection and results from class switching from IgM to IgG.

Because some IgG antibody may already be present in a patient's acute-phase serum specimen, it is generally necessary to quantify the concentration of antibody in both the acute-phase and the convalescent-phase specimens. In acute and convalescent antibody titer testing, sera are generally tested as twofold dilutions in a series of tubes. A fourfold increase (two doubling dilutions) in total antibody titer between acute-phase (acute antibody titer) and convalescent-phase (convalescent antibody titer) sera is considered diagnostic for a current infection. It is important that both sera be tested at the same time because most serologic tests have an inherent variability that can alter the titer by at least twofold. Testing the sera at the same time reduces this variability.

Disadvantages of acute and convalescent serum testing include return visits for the patient to have blood drawn and the time needed to detect an increase in antibody titer. In addition, false negatives are possible if sera are collected too early in the course of the disease. In this case, an acute-phase sample would be negative, and the convalescent-phase sample would be positive. This scenario is referred to as **seroconversion**. Although seroconversion usually occurs within 2 to 3 weeks after onset of illness, it may be delayed in certain patients or types of infection.

Some commercial diagnostic tests are designed without the need to perform serial dilution and establishment of titers. Instead, undiluted serum or a single serum dilution is tested. In these situations, the determination of a single positive result suggests, but does not always prove, current infection. Generally, if serologic diagnosis of current infection on a single serum specimen is to be attempted, an IgM assay as well as an IgG-specific assay should be performed. If both assays are negative, the patient probably has not been infected. If both assay results are positive or just IgM antibody is detected, the patient probably has been infected recently. If just IgG antibody is present, the patient probably has been infected in the past and does not have a current infection. It is very important that laboratory scientists completely understand all of the performance characteristics of a commercial serologic test system.

Monoclonal antibodies

When an animal is exposed to a single antigen, antibodies to different epitopes on the antigen can be produced. These antibodies are called *polyclonal antibodies* because each antibody was derived from a different clone of plasma cells. In serologic testing, antibodies can be used to detect antigens in patient samples. The problems with polyclonal antibodies are low specificity because the antibody solution contains multiple antibodies with different specificities, which can result in a high level of cross-reactivity.

The problems with a polyclonal antibody can be avoided with the use of a **monoclonal antibody**. This antibody is derived initially from one cell that has been exposed to one epitope. This cell divides, producing a clone of identical cells, and then produces an antibody specific to this one epitope. Monoclonal antibodies are rarely naturally occurring and are usually associated with some type of abnormal immune disease process. The production of monoclonal antibodies in the laboratory has become commonplace. It is used extensively in serologic testing in which

the identification or quantification of an antigen is the primary goal. These antibodies have strong binding kinetics to specific epitopes on antigens (**avidity**) and can discriminate among closely related antigenic determinants (specificity). However, because monoclonal antibodies are very specific, they have low sensitivity. If a bacterial population contains an altered or mutated form of an antigen, it may not react to the monoclonal antibody, resulting in a **false-negative** test result.

Monoclonal antibodies are purified from a single clone of cells. In 1975, George Köhler developed the technique for producing monoclonal antibodies in the laboratory. In this method, a scientist injects a crude antigen mixture into a mouse or other animal and then selects a clone of plasma cells that produces a specific antibody against an antigen. This process of producing a monoclonal antibody can take 3 to 6 months. A single antibody-producing lymphocyte is fused to a myeloma cell to form a hybrid. This hybrid proliferates to form a cell line called a **hybridoma** (Fig. 10.2). Monoclonal antibodies have also been used to treat infectious diseases such as Ebola and coronavirus disease 2019.

Fig. 10.2 Preparation of polyclonal and monoclonal antibodies.

Antibody specificity and cross-reactivity

Most antigen-antibody reactions show high specificity; that is, the antigen-binding sites on the antibody molecule react with specific epitopes and not with other antigens containing different epitopes. However, some antigens from different microorganisms are similar, and a host may respond by producing antibody, not only to the invading organism but also to antigenically similar organisms. These antibodies are said to *cross-react*, which may lead to misinterpretation of serologic tests. Antibodies produced in response to one molecule that also react against an antigen from an unrelated source are called **heterophile antibodies**. Because of antibody cross-reactivity, it is often best to perform a battery of serologic tests using the organisms known to show cross-reactivity and to do so with paired sera. An example of this type of testing would be a fungal antibody panel consisting of tests for histoplasmosis, blastomycosis, and coccidioidomycosis.

False-negative and false-positive serologic results

An ideal serologic test would have 100% diagnostic accuracy; that is, it should be positive on all specimens from patients with the infection and negative on all specimens from patients without the infection by the specific agent (Fig. 10.3A). In practice, serologic tests, like other laboratory tests, fall short of this ideal. The accuracy of diagnostic tests is measured in terms of *sensitivity*, *specificity*, *positive predictive value*, and *negative predictive value*. See Chapter 5 for a discussion of these terms.

A false-negative serologic test is defined as a negative result for a patient who really is infected. It may occur for many reasons. A patient may be immunocompromised and unable to respond to an immunogenic stimulus. This might be the case in an individual with a congenital or acquired immunodeficiency disease or in a patient receiving either immunosuppressive therapy after organ transplantation or cancer chemotherapy. In addition, neonates may not always respond to an infectious agent because of an immature immune system. For some infections, such as Lyme disease and Legionnaires' disease, antibody titers may not increase until months after acute infection, leading to false-negative serologic test results on serum samples collected too early in the course of the infection. Not all individuals react the same way to immunogenic stimuli because of the inherent genetic differences in the immune system among individuals.

A different type of false-negative result may occur in assays designed specifically to detect IgM antibody. It might be a result of competition for antigen-binding sites between IgG and IgM antibodies in a serum specimen from a patient with high levels of IgG and relatively low levels of IgM (see Fig. 10.3B). IgM antibody tests are sometimes performed on the serum of a newborn to diagnose an in utero infection. A newborn's serum specimen might contain maternal IgG to a specific infectious agent as well as low levels of fetal IgM. The IgG antibody molecules bind to antigen in the assay and block IgM binding, producing a false-negative IgM result. Most assays designed to detect

Fig. 10.3 Causes of false-positive and false-negative immunoglobulin M (IgM) assays. **A**, True-positive IgM assay. **B**, False-negative IgM assay. Excess antigen-specific immunoglobulin G (IgG) inhibits antigen-specific IgM from binding. **C**, False-positive IgM assay. Rheumatoid factor (RF) binds to antigen-specific IgG and is detected with labeled anti-IgM antibody. A, Antigen; F, fluochrome or another label.

IgM antibody include some initial procedure to separate IgG physically from IgM or to “capture” IgM in the assay and then remove IgG.

A false-positive serologic test result is a positive result for a patient who is not infected by the specific agent for which the test is designed. It might occur from the production of cross-reacting antibody, as discussed previously, or from reactivation of a latent organism resulting from infection by a different organism. Influenza A virus infection can cause reactivation of latent cytomegalovirus (CMV) with a concomitant increase in CMV antibodies. False-positive IgM antibody assays can also occur. These are caused by the presence of RF activity in the serum. RF is generally an IgM antibody that is produced in some individuals and binds to the Fc region of the individual's own IgG. IgM RF cannot be readily differentiated from organism-specific IgM in some serologic tests. If both organism-specific IgG and RF (but not organism-specific IgM) are present in a patient's serum specimen, the serologic test result may be falsely positive for an organism-specific IgM antibody (see Fig. 10.3C). Finally, individuals receiving intravenous immunoglobulin, a product prepared by pooling large quantities of plasma from multiple volunteer donors, may show a specific antibody to various infectious agents because of passive transfer, not active infection. Laboratory personnel

must be aware of this possibility and any therapy that may be of significance in interpreting serologic test results for a specific patient specimen.

Population studies

Serologic tests for a specific infectious agent or a panel of agents may be performed to determine the percentage of individuals previously exposed or infected with the agents in a geographic area. This information provides epidemiologists and public health officials with information about how widespread an infectious agent is in a given area. Such studies have shown that the fungus *Histoplasma capsulatum*, which causes histoplasmosis, is widely distributed in the Ohio River Valley and that the bacterium *Borrelia burgdorferi*, which causes Lyme disease, is common in the upper Midwest, New England, and Middle Atlantic states. Similarly, serologic studies performed on animals that are reservoirs for human disease may alert public health officials that a disease (e.g., West Nile virus) may be active in the area and may pose a threat to humans.

Immune status testing

In several situations, it may be important to determine whether an individual is immune, through either previous infection or immunization, to a specific infectious disease. For example, women considering pregnancy should be screened for rubella and CMV antibodies; both infections can cause morbidity or mortality to the fetus. It is generally recommended that all women of childbearing age be tested for their rubella immune status; if it is negative, they should be vaccinated before considering pregnancy.

An additional situation in which immune status testing might be considered is organ or bone marrow transplantation. CMV may reside latently in leukocytes of donor tissue and can cause significant disease in a nonimmune recipient. It is recommended that a CMV-negative transplant recipient receive tissue and blood products from a CMV-negative donor.

Congenital infections

Serologic testing is often used to help diagnose congenital infections (acquired in utero) in a newborn; some infectious agents can cross the placenta and cause fetal infections. Such infections might cause only minimal symptoms in the mother during pregnancy and may go undiagnosed at the time. However, if the mother is nonimmune, the infection can be significant to the fetus. The agents most commonly found are the TORCH agents: *Toxoplasma gondii*, which causes toxoplasmosis; other (*Treponema pallidum* subsp. *pallidum*, which causes syphilis; parvovirus B19); rubella virus; CMV; and herpes simplex virus.

Testing the mother's serum for IgG antibody is useless unless she was screened prenatally or early in pregnancy and antibody test results were negative. Because the TORCH agents are common infectious agents, many individuals have IgG antibody remaining from previous infections. Similarly, testing for IgG antibody in the newborn is of no value because maternal IgG crosses the placenta and is present in neonatal serum. Testing for maternal IgM antibody is likewise of little value (unless infection occurred near the time of delivery)

because it may be undetectable 1 or 2 months after infection. Therefore IgM antibody detection on neonatal serum is the method of choice for serologic diagnosis of congenital infection by one of the TORCH agents.

Antigen detection

Antibody detection can require a significant length of time to become positive. Direct antigen-based tests are generally considered to be less sensitive than culture; however, they can yield diagnostic information much sooner, many within 30 minutes. This shorter time is extremely important in treatments that require documentation of the presence of a specific agent.

Numerous infectious agents produce antigens that can be identified from almost any body fluid (serum, urine, sputum, CSF, or exudates) or cellular material. The modern era of direct antigen detection began in the mid-1970s. The capability to produce large quantities of highly specific monoclonal antibodies led to a sharp increase in production of rapid diagnostic assays. Direct microbial antigen detection is the process by which microbial antigens, such as capsular polysaccharide or cell wall components, are identified in specimens obtained from an infected host. These antigens can be recognized by and combine specifically with antibody molecules to form stable immune complexes.

The process of antigen detection involves mixing a clinical specimen with an antibody preparation specific for the antigen of interest. If the microbial antigen is present in the specimen, an antigen-antibody interaction occurs, forming an immune complex. This complex can be detected by many techniques. Some methods take advantage of the fact that antibody molecules are polyvalent—they have two or more antigen-binding sites—and can combine with two or more antigens (Fig. 10.4). Many techniques use indicator molecules such as enzymes and substrate, **fluorochrome** excitation, or chemiluminescence. The tests used to detect these proteins (antigens) are similar to the tests used in the detection of an antibody.

Principles of immunologic assays

Precipitation assays

Precipitation reactions involve the diffusion of soluble antigen and antibody. At a critical point, when the concentrations are optimal, a visible precipitate forms that is composed of an insoluble complex of antigens and antibodies. Precipitation reactions are most stable when performed in an agarose gel; however, some are conducted in liquid. Precipitation methods with diagnostic significance for infectious diseases are **double immunodiffusion**, **radial immunodiffusion**, and **flocculation** tests.

Double immunodiffusion

Immunodiffusion refers to the movement of antigens and/or antibodies toward one another. In the *double immunodiffusion* or *Ouchterlony gel diffusion* (Fig. 10.5) technique, cylindrical holes or wells are cut out of an agarose gel and spaced appropriately in a small Petri dish. For antibody detection, a known crude or purified antigen extract of a microorganism is placed in one well of the agar plate, and a patient's serum sample is added to a nearby well. The antigen and antibody molecules in solution diffuse out of the wells and through the porous agarose. If antibody specific for the antigen is present, the two components combine at a point of optimal concentration called the **zone of equivalence** and produce a visible precipitin band, or line

Fig. 10.5 Ouchterlony plate. A serum specimen containing an unknown antibody is placed in one well (e.g., well 4), a known antigen of interest is placed in an adjacent well (well 3—positive control), and a known antiserum to the antigen is placed in another adjacent well (well 7—positive control). The antigen and antibody molecules in the solution diffuse from the wells and through the porous agarose. If the unknown serum contains antibody to the known antigen, a precipitin band forms at a point of optimal concentration of each component. This precipitin band is called a *line of identity*.

of precipitation. Because the test relies on passive diffusion of molecules, diffusion is slow and is not generally amenable to rapid diagnosis. Reactions may take 48 to 72 hours to develop. It is most commonly used to detect fungal exoantigens or serum antibodies. Double immunodiffusion is primarily limited to detecting antibodies to fungal pathogens, including *H. capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*.

Single radial immunodiffusion

With single radial immunodiffusion, known antibody is evenly distributed in agar placed into a plastic dish. Wells are cut in the agar, and a sample is added to the wells that may contain antigen recognized by the antibody. The antigen passively diffuses through the agar and forms a precipitate ring at the zone of equivalence with the antibody. The diameter of the zone of precipitation is directly proportional to the concentration of the antigen. This technique can be used to quantify antigen concentration, but it is not used much today, having been replaced by quicker methods.

Flocculation

Flocculation tests are a variation of precipitation tests that also have some properties of agglutination assays. In these tests, because of the chemical nature of the antigen (not truly soluble), the antigen-antibody reaction forms a microscopically visible clump or precipitate of fine particles that remain in suspension. The most important applications for flocculation tests in antibody detection relate to syphilis serology. Following infection with *T. pallidum*, the body reacts by developing two classes of antibodies: (1) specific or treponemal antibodies directed against *T. pallidum* antigens and (2) non-specific or nontreponemal antibodies directed against normal host tissue. These nontreponemal antibodies, also referred to as **reagin antibodies**, are detected by flocculation reactions. Syphilis serology is discussed later in this chapter.

Nephelometry

Nephelometry has recently gained popularity as a sensitive method to detect immune complexes formed in liquid. This method is based on the light-scattering ability of insoluble particles. A beam of light, incident light, is passed through a tube containing the mixture. The amount of scattered light is measured at an angle, typically 90 degrees, to the incident light. The scattered light is directly proportional to the concentration of immune complexes. By using standards, it is possible to quantify the immune complexes, referred to as *quantitative nephelometry*. A special instrument, a nephelometer, is required. The method can be applied to measuring an antibody or an antigen and analytes, such as C-reactive protein.

Agglutination assays

Agglutinating antibodies react with antigens on the surface of microscopic particles to form visible clumps. Agglutination tests can be performed in test tubes, but they are generally performed on the surface of glass, plastic, or cardboard slides. Agglutination tests for antibody detection can be classified as either direct (natural carrier particle) or indirect (artificial carrier particle) agglutination. **Indirect agglutination** is also

referred to as *passive agglutination*. **Reverse passive agglutination** uses an antibody attached to a particle to detect an antigen. In contrast with precipitation reactions, in agglutination reactions, either the antigen or the antibody is bound to a particulate carrier (making it insoluble) before forming an immune complex.

Serologic tests based on direct particle agglutination take advantage of antigens that naturally occur on biological cells. Most commonly, these cells are whole bacteria or erythrocytes. In whole bacterial cell agglutination, surface antigens found on the bacterial cell wall or capsule allow cross-linking and macroscopic agglutination of the cells in the presence of a specific antibody. Serotyping enteric pathogens such as *Salmonella* is based on the detection of bacterial surface antigens using commercially prepared sera. Direct particle agglutination of erythrocytes is used in immunohematology to determine an individual's blood type.

Latex agglutination

Various antigens can be passively or chemically coupled to naturally occurring particles like erythrocytes or to synthetic particles such as latex (polystyrene) beads. These beads, usually about 1 μm in diameter, can be a variety of colors and enhance the visibility of agglutination reactions. In this arrangement, the particle can be agglutinated by specific antibody found in a patient's serum specimen. The antigen-coated latex beads form a homogeneous milky suspension, which, when mixed with a specimen containing a specific antibody, results in antigen-antibody binding. However, this primary binding between antigen and antibody molecules does not produce a visible agglutination (clumping) reaction. The antibody must interact with the antigen on two different latex beads (secondary binding) to produce agglutination.

In reverse passive agglutination, each latex bead can contain thousands of monoclonal or polyclonal antibody molecules. When mixed with a specimen that contains antigens specific for the antibody on the latex beads, antigen-antibody binding results. However, antigen molecules are cross-linked by the antibody-coated latex beads only if the antigen molecules contain multiple epitopes, as is common for high-molecular-weight polysaccharides, proteins, or microorganisms. This secondary cross-linking of antigen and antibody molecules results in a macromolecular lattice and produces a visible agglutination reaction (Fig. 10.6).

Latex agglutination (LA) assays are generally conducted on a treated cardboard or glass slide using a liquid specimen and volumes of about 50 μL for both the clinical specimen and the latex bead suspension (Fig. 10.7). The specimen and latex suspension are mixed thoroughly, and the slide is rocked or rotated by hand or with a mechanical device for 2 to 3 minutes before reading with appropriate lighting and the naked eye. The reaction depends on many variables; therefore standardization is imperative. Variables include latex particle size, avidity of the antibody, isotype of the antibody (IgM or IgG), reaction temperature, pH, ionic strength of the solution, and concentration of antigen in the specimen. IgM is a pentamer and is a more effective agglutinin than IgG. Microbial polysaccharide or protein can be detected at levels of 0.1 ng/mL.

The strength and rapidity of the reaction vary depending on the test conditions and, most importantly, on the antigen concentration in the specimen. With a high antigen concentration

Fig. 10.6 Alignment of antibody molecules bound to the surface of a latex particle and latex agglutination reaction.

Fig. 10.7 Commercial latex agglutination test slide showing reaction of controls and a patient's cerebrospinal fluid with latex reagents specific for *Haemophilus influenzae* serotype b (Hib), *Streptococcus pneumoniae* (Sp), group B streptococcus (GBS), and five different serogroups (groups C and W135, groups A and Y, and group B) of *Neisseria meningitidis* (Nm). Note the positive reactions with each test latex reagent and positive control (P) as well as the positive reaction with the patient's specimen and Hib test latex. (Courtesy BD Diagnostic Systems, Sparks, MD.)

in the test sample, a maximum agglutination reaction (4+ on a 1+ to 4+ scale) may occur in only a few seconds. In the absence of a specific antigen, the latex suspension remains homogeneous and milky; that is, no agglutination is seen.

Controls must accompany the testing of patient specimens (Table 10.2). These controls include (1) a positive antigen control (a solution containing the known antigen of interest), (2) a negative antigen control (a solution not containing the antigen), and (3) a control latex suspension to detect the presence

Table 10.2 Interpretation of latex agglutination test controls and patient specimens

Reaction number	Test specimen	Agglutination reaction		
		Test latex	Control latex	Interpretation
1	Positive antigen control	+	0	Control okay
2	Negative antigen control	0	0	Control okay
3	Patient A	+	0	Positive test
4	Patient B	0	0	Negative test
5	Patient C	+	+	Nonspecific agglutination

+, Agglutination; 0, no agglutination.

of nonspecific agglutination reactions. The control latex involves testing the patient specimen with latex beads coated with an immunoglobulin whose specificity is not directed to the test antigen. This nonimmune serum is generally obtained from the same animal species in which the specific antibody was made. A nonspecific agglutination reaction occurs when the patient's specimen reacts with both the test and the control latex. When such reactions occur, the test is uninterpretable. A positive test result requires that the test latex, but not the control latex, agglutinate the patient specimen.

LA assays for microbial antigens, similar to other laboratory tests, are subject to false-negative and false-positive reactions compared with culture. False-negative reactions (negative antigen test result, positive culture) may be caused by the presence of antigen in the specimen at concentrations below the test detection limit. **Prozone** occurs when the relative concentration of antibody exceeds the antigen concentration. In this situation, each antigen combines with one or two antibody molecules, and cross-linking between the antigen and antibody does not occur. In addition, false-negative reactions can occur with antigen excess; this is called **postzone**. When the antigen concentration exceeds the relative antibody concentration, cross-linking between the antigen and antibody does not occur, and a proper lattice does not develop. Some test kits for antigen require all negative results be retested with a diluted sample to rule out postzone.

False-positive reactions (positive antigen test result, negative culture) are more difficult to explain; they may be caused by the presence of cross-reacting antigens or nonviable organisms in the specimen. Antigen detection tests do not require viable microbes. Antibody-coated latex suspensions can agglutinate viable or nonviable organisms, microbial components such as cell wall or membrane fragments, or soluble antigens such as bacterial capsular polysaccharide. Thus an apparent false-positive latex test result may actually represent a true-positive result for disease in a patient with a negative culture.

Numerous specimen pretreatment procedures can be used to eliminate or minimize nonspecific agglutinations, presumably by removing or inactivating factors in the specimen

responsible for these reactions. These procedures include specimen centrifugation to remove particulate material, boiling to inactivate protein constituents (acceptable when test antigen is a heat-stable polysaccharide), and passing the specimen through a membrane filter. Some specimens, such as urine, may be concentrated by centrifugation or membrane filtration before testing. Filters typically trap or exclude high-molecular-weight antigenic materials while allowing water and small compounds to pass through. These concentration methods increase the sensitivity of the test. Pretreatments are less frequently required as commercial latex kits become more specific and sensitive.

The advantages of LA tests are the availability of good-quality reagents in complete kit form, good sensitivity, relative rapidity, and ease of performance. Disadvantages include subjectivity in reading endpoints and nonspecific reactions resulting from interfering substances in clinical samples. The LA test is one of the most widely used antigen detection methods in the clinical laboratory. In many clinical laboratories, serogroup identification of the β -hemolytic *Streptococcus* spp. from culture plates is routinely performed using LA test kits. The sensitivity for *Streptococcus pyogenes* in throat swabs is 70% to 96%. Commercial antibody-detection serologic tests based on LA are available for many viral infections, including CMV, rubella, and infectious mononucleosis (heterophile antibody), and a few bacterial (streptococcal, mycoplasmal), fungal (candidal), and parasitic (toxoplasma) infections. Because of low sensitivity, routine use of LA tests for the detection of *Streptococcus agalactiae* in CSF and urogenital tract specimens is no longer recommended.

Staphylococcal coagglutination

Similar to LA, staphylococcal coagglutination, or simply **coagglutination**, uses particle-bound antibodies to enhance the visibility of antigen-antibody reactions. Instead of a latex bead, intact formalin-killed *Staphylococcus aureus* cells (typically Cowan 1 strain) are used. The cell wall of this strain of *S. aureus* contains a large amount of protein A, which binds the Fc portion (crystalline fragment, back of the heavy immunoglobulin chains) of the IgG antibody molecule. This leaves the fragment of antigen-binding (fab) sites of the molecule available to react with specific antigens (Fig. 10.8). It has been estimated that each staphylococcal cell has about 80,000 antibody-binding sites. The actual number of antibody molecules bound to the staphylococcal cell is limited by steric hindrance. However, coating is sufficient to render the product of clinical utility in direct antigen tests.

Coagglutination reactions are prepared by mixing antibody-sensitized staphylococcal cells with a solution containing the antigen of interest on a slide or card (Fig. 10.9). Coagglutination procedures appear more susceptible to nonspecific agglutination reactions, and specimen preparation is important. This is particularly true for testing serum specimens, probably because staphylococcal cells may bind human IgG in test serum specimens and subsequently be agglutinated by the presence of RF (anti-IgG IgM) in the serum. Coagglutination is highly specific but may be less sensitive than LA in detecting small quantities of antigen. Therefore these reagents are often used to confirm the identification of bacterial colonies on culture plates but not for rapid antigen detection from clinical specimens.

Fig. 10.9 Commercial coagglutination test card showing positive (1) and negative (2 and 3) reactions. The blue color is an indicator dye added to make the agglutination reaction easier to read against a white background.

Hemagglutination

In passive or indirect hemagglutination (IHA), microbial antigens are attached to erythrocytes after chemical treatment of the cells with tannic acid, chromic chloride, glutaraldehyde, or another substance that promotes cross-linking of the antigens. The sensitized cells can be reacted with a patient's serum specimen to detect agglutinating antibody. This assay method is rarely used today. Cells such as erythrocytes have a surface negative charge known as the **zeta potential**. If bacterial or fungal cells have the same charge, they will repel. For agglutination to occur, antibodies binding to the cells must be sufficiently large to span the cells and overcome the charges. IgM, because it is a pentamer, is better at agglutinating erythrocytes than IgG. The repulsion of cells by the zeta potential can be affected by pH, low ionic salt solution, and fluid viscosity.

An example of a direct hemagglutination test is the detection of heterophile antibodies in the acute stage of infectious mononucleosis, resulting from Epstein-Barr virus (EBV) infection. In the case of infectious mononucleosis, human heterophile antibody reacts with horse, ox, and sheep erythrocytes. In the appropriate setting, heterophile antibody testing is diagnostically useful. Specially treated horse erythrocytes provide the antigen, and the agglutination test is read on a slide or card (BBL MonoSlide; Beckton-Dickinson, Franklin Lakes, NJ). Another company markets dyed, color-enhanced

Fig. 10.10 Sure-Vue Mono test kit for the detection of heterophile antibodies produced during infectious mononucleosis. (Courtesy Biokit USA, Lexington, MA.)

horse erythrocytes for better contrast (ColorCard Mono-Test; Alere, Waltham, MA). Newer assays are based on heterophile antigens attached to latex particles (Sure-Vue; Biokit USA, Lexington, MA) (Fig. 10.10).

Hemagglutination inhibition

A laboratory test that has great historic significance to diagnostic serology, particularly to viral infections, is the hemagglutination inhibition (HI) test. This test takes advantage of the fact that many viral agents, including rubella and influenza viruses, have surface antigens that can agglutinate erythrocytes from certain mammalian species. Antibodies present in sera can bind to the virus and inhibit the agglutination reaction. The HI antibody titer is the highest dilution of the patient's serum that completely inhibits agglutination of the erythrocytes by the virus. Enzyme immunoassays (EIAs) are frequently used to diagnose influenza virus infection as well. These assays have the advantage of being able to differentiate IgG from IgM.

Liposome-mediated agglutination

Liposome-mediated agglutination involves the use of liposomes, which are single-lipid bilayer membranes that, under appropriate conditions, form closed vesicles ranging in size from 1 to 20 μm in diameter. In their manufacture, antigen or antibody molecules can be incorporated into the surface of the membrane and be available for interaction with the corresponding molecule (Fig. 10.11). In addition, the liposome vesicle may be constructed with a chemical dye or bioactive molecule trapped in the interior. The colored dye allows easy visual detection of lattice formation and agglutination between liposome-bound antibodies and antigens. Alternatively, combining dye-containing liposomes and latex beads, both of which contain the reactive antibody on the surface, may increase the sensitivity of LA. Another potential

advantage of liposome technology is in its application to immunoassays other than particle agglutination that make use of the ability of the liposome to carry reactive chemicals. Liposomes have yet to reach their full potential as diagnostic reagents in the clinical laboratory. Particle agglutination methods are compared in Table 10.3.

Neutralization assays

Neutralization assays for antibody detection are based on the interaction of a biologically active antigen with antibodies that can block or inactivate the activity of the antigen. Not only involved in serologic tests, neutralizing antibodies play an important role in functioning as protective antibodies *in vivo*. For example, immunity to numerous viruses depends on circulating antibodies that can neutralize, or block the infectivity of viruses that reach the bloodstream. Neutralization probably occurs because the antibody binds to the viral particle and blocks the interaction between viral adhesion molecules and receptor sites on target cells. Neutralizing antibodies to viruses can be measured *in vitro* using cell cultures.

In viral neutralization, a patient's serum sample is serially diluted, and each dilution is mixed with a standard amount of a known virus suspected of causing disease in the patient. The virus-serum mixtures are inoculated to a series of cell

culture tubes or flasks. If the patient's serum contains neutralizing antibodies to the virus, the antibody blocks viral infection and prevents the **cytopathic effect** (CPE) of the cells. CPE is the visual changes occurring in cell monolayers caused by viruses or toxins. The neutralizing antibody titer is the highest dilution of the patient's serum to completely block the CPE. For diagnosis of current disease, acute-phase and convalescent-phase sera should be tested, and a fourfold titer increase should be demonstrated.

Viral neutralization assays are highly sensitive and specific, but they also are technically demanding and require the use of active virus and cell cultures. They are not commonly used serologic tests today, but neutralization tests are valuable in identifying an unknown virus with known antibody. Other examples of neutralization assays are the HI assay (previously discussed) and the antistreptolysin O (ASO) neutralization test to detect antistreptococcal antibodies.

Labeled immunoassays

Immunofluorescent assays

Immunofluorescent assays are a method for rapid antigen and antibody detection in the clinical laboratory. Results are generally available within 15 to 60 minutes. When specific monoclonal or polyclonal antibodies are conjugated with fluorescent dyes (*fluorochromes*), they can be visualized with a fluorescence microscope. Labeled antibodies are called **conjugates** because the antibody is conjugated (linked) to a label. Fluorochromes are chemicals that absorb light of one wavelength and emit light of a different wavelength, thus changing color. The fluorescence microscope uses an epiluminescent (incident) light system of vertical illumination, wavelength filters, and a dichroic mirror (Fig. 10.12). The dichroic mirror allows passage of light at an excitation wavelength from the light source to the specimen. The mirror also allows passage of the emission (longer) wavelength light from the labeled source to the objective lens. This emitted, or excited, wavelength light appears as a bright color depending on the dye. A commonly used fluorochrome is fluorescein isothiocyanate (FITC), which, when excited, emits a bright apple-green fluorescence (Fig. 10.13) that can be seen against a black background.

Detection techniques may be direct or indirect. In the **direct fluorescent antibody** (DFA) test, the clinical specimen containing the antigen of interest is fixed onto a glass slide with formalin, methanol, ethanol, or acetone. Fixation renders mammalian cell membranes permeable to the stains. The antigen-specific labeled antibody is applied to the fixed

Fig. 10.11 Diagram of liposome particles showing bilipid layer structure. Either antibody (A) or antigen (B) can be attached to the surface of the liposome. The interior of the liposome can carry reporter molecules (e.g., dyes, enzymes).

Table 10.3 Comparison of particle agglutination methods			
Agglutination method	Particle type	Nature of antibody-binding to particle	Diagnostic utility
Latex agglutination	Latex beads	Nonspecific absorption or chemical coupling	Most widely used agglutination method for direct detection
Staphylococcal coagglutination	Formalin-fixed staphylococci	Fc portion of IgG molecule binds to protein A on staphylococcal cell wall	Used for antigenic identification of bacteria in culture
Liposome-mediated agglutination	Liposomes	Chemical coupling	Newer method; limited applications of commercial tests
IgG, Immunoglobulin G.

specimen, incubated, washed, and examined with a fluorescence microscope. If the antigen was present in the clinical specimen, the labeled antibody (conjugate) binds to the antigen, and fluorescence is seen (Fig. 10.14A). Immunofluorescent staining allows for rapid visualization of infected tissue, cell culture, body fluids, and swab specimens.

When the infectious agent does not produce enough antigen for detection in body fluids, direct testing of host cells must be considered. The use of a specific antibody for the infectious agent enables the detection of the agent inside the infected host cells. Direct immunofluorescence techniques are the assay of choice under these conditions. The DFA test is used to detect *Bordetella pertussis*; *Legionella pneumophila*; *Giardia duodenalis* (synonyms *G. lamblia*, *G. intestinalis*); *Cryptosporidium* spp.; *Pneumocystis jirovecii*; herpes simplex virus; CMV; varicella-zoster virus; and commonly isolated respiratory viruses such as parainfluenza virus, influenza virus, adenovirus, and respiratory syncytial virus (RSV) in clinical specimens. Immunofluorescent assays can also be used for confirmation of viruses isolated in cell cultures.

In the **indirect fluorescent antibody (IFA)** test for an antibody, whole microbial cells (bacteria, fungi, protozoan parasites) or virus-infected mammalian cells are washed and fixed

Fig. 10.14 Fluorescent antibody test for identification of tissue antigens or their antibodies. **A**, Direct fluorescent antibody. The antigen-specific–labeled antibody is applied to the fixed specimen, incubated, washed, and visualized with a fluorescence microscope. **B**, Indirect fluorescent antibody. A second fluorochrome-labeled antibody specific for the first unlabeled antibody is applied. (From Goering, R. V., et al. [2008]. *Mims' medical microbiology* [4th ed.]. London: Mosby.)

at a specific density to glass slides. Frequently with commercially prepared assays, cells are placed into small wells on the glass slide, and different patient samples are added to individual wells. Fixation is usually accomplished with methanol, ethanol, or acetone.

The patient's serum can be serially diluted, applied to the fixed-cell preparations, and incubated at 22° to 37°C in a humid environment to prevent drying, allowing antigen-antibody binding to occur. The slides are then washed with a buffered solution to remove the unbound antibody before application of antihuman IgG or IgM antibody that is fluorescently labeled (conjugate) and reactive with human immunoglobulin. The slides are incubated again and washed, air-dried, and viewed using a microscope fitted with a light source and filters to excite the fluorochrome (see Fig. 10.14B). If the specific antibody to the infectious agent's antigen is present in the patient's serum, the antibody binds, and secondary binding by the conjugate occurs. The cells fluoresce and are scored on a semiquantitative scale as positive (1+ to 4+) or negative. The titer is the reciprocal of the highest dilution of the patient's serum giving a minimum level of fluorescence (often at 2+ or greater).

The IFA test is also useful in detecting IgM-specific or IgG-specific antibody by using an FITC-labeled second antibody that is highly specific for human IgM or IgG. As with any IgM test, IFA for IgM is subject to false-negative results because of excess IgG and to false-positive results because of RF. To avoid these problems, IgG should be physically removed or functionally inactivated for IgM-specific assays.

The utility of DFA and IFA tests is limited by many factors, including the labor-intensive nature of the procedures, the requirement for a fluorescence microscope, the need for a darkroom, and the subjective interpretation involved in reading the slides. The procedures are not easily amenable to automation. Finally, fluorescence fades over time. The method is still sometimes used for the serologic diagnosis of infectious diseases caused by the TORCH agents, *L. pneumophila*, *B. burgdorferi*, *Rickettsia rickettsii*, and *M. pneumoniae*. The detection of *T. pallidum* antibodies using the fluorescent treponemal antibody absorption (FTA-ABS) test (discussed later in this chapter) is being replaced by assays that are easier to perform. The principle of IFA is also applied to the detection of autoantibodies (antinuclear antibodies) in the diagnosis of systemic lupus erythematosus and other autoimmune diseases.

Numerous variations of the IFA test have been developed. The basic objective in most of these procedures has been to increase sensitivity while maintaining specificity of the assay. One example of such a procedure is the double IFA test (Fig. 10.15). This method uses a second, unlabeled antihuman IgG or IgM antibody to bind to microbial-specific antibodies in a patient's serum. The FITC-labeled antibody is directed at the second antibody. The additional step amplifies the reaction because multiple molecules of the second antibody can bind to the patient's antibodies, providing additional binding sites for the FITC-labeled antibody. Newer serologic assays are often evaluated by comparison with IFA procedures. The IFA test is also quickly adaptable to studying serologic response to newly discovered infectious agents.

Enzyme immunoassays

Because of the drawbacks of immunofluorescent assays, antibodies have been conjugated to other labels. EIA is an alternative to immunofluorescent assays for detecting antigens and antibodies in clinical samples. Instead of labeling an antibody with a fluorochrome, EIA uses enzymes, such as horseradish peroxidase or alkaline phosphatase, conjugated to antibodies so both enzymatic and antigen-binding activities are preserved. When the appropriate substrate is added to the antigen-conjugated antibody complex, the enzyme catalyzes the production of a visible (colored) product that can be qualitative (positive or negative) or quantified spectrophotometrically. These products do not fade with storage and can be

detected by simple light microscopy. The ability to visualize and evaluate reactions gives a high level of certainty to the procedure.

EIAs are widely used for the serologic diagnosis of infectious diseases. They are popular for many reasons, including (1) the availability of commercial EIA kits for many infectious agents; (2) the adaptability of EIA tests to automation, allowing more tests to be performed in shorter times; and (3) the objective interpretation of test results with colored end products that can be read by a spectrophotometer. Several commercial products are tailored for high-volume laboratories; others are designed for single-use applications on individual patient specimens.

Commercially developed EIAs for the diagnosis of infectious agents typically require a solid phase for attachment of an antigen or antibody. Various solid matrix platforms are available that include individual wells of polystyrene microtiter plates (Fig. 10.16A), spherical plastic beads, or magnetic beads (see Fig. 10.16B). The solid matrix allows for washing of the sample and reagent to decrease nonspecific binding or background activity.

When performing an EIA to detect an antigen, the solid phase contains a capture antibody bound to the matrix. A clinical sample is added, and if the antigen of interest is present in the sample, it forms a stable immune complex with the antibody bound to the matrix. Unbound sample is removed by washing, and a second antibody specific for the antigen is added. In the direct method for antigen detection, this second antibody is conjugated to an enzyme. In the indirect method, a second nonconjugated antibody is added and washed, and then a third antibody specific for the second antibody is added. The third antibody is conjugated to the enzyme and is directed against the Fc portion of the unlabeled second antibody.

In either method, after the conjugate is added and washed, the enzyme-specific substrate is added. After a specified time, a stop reagent is added to block enzyme activity. The amount of colored product is directly proportional to the amount of enzyme-bound conjugate and antigen present in the original clinical sample. Both methods of detection are described in a step-by-step manner in Fig. 10.17. The methods described are often called **direct sandwich immunoassay** and **indirect sandwich immunoassay**. The advantage of the indirect sandwich immunoassay is the need for only one enzyme-conjugated anti-immunoglobulin antibody (third antibody) that can be used in different assays to detect various antigens. A disadvantage is that heterophile antibodies can produce false-positive or falsely increased results. The heterophile antibody can behave like the antigen, binding to both the capture and the signal antibodies.

In **competitive immunoassays**, an unlabeled patient antibody competes with a commercially prepared labeled antibody for a limited number of binding sites to an antigen. The clinical specimen and labeled antibody are added simultaneously, and after appropriate time, they reach equilibrium. The more antibodies present in the clinical sample, the fewer labeled antibody molecules bind. After a wash step, the enzyme substrate is added. The color produced is inversely proportional to the antibody concentration in the specimen. In other words, the greater the color intensity, the lower the patient antibody concentration. This method can also be applied to determining antigen

Fig. 10.15 Double indirect fluorescent antibody tests for antibody detection.

Fig. 10.16 Principle of direct solid-phase immunosorbent assay. **A**, Solid-phase surface is a microtiter well. **B**, Solid-phase surface is a bead.

(analyte) concentration. A capture antibody is attached to a solid phase, and a patient's sample containing unlabeled antigen is added with the labeled antigen. After incubation, the substrate is added, and again, the color intensity is inversely proportional to the antigen concentration. Competitive assays have greater sensitivity than noncompetitive assays and are frequently used to measure the concentration of analytes, such as hormones.

Commercial companies have produced good-quality EIA kits for detection of various microbial antigens. Conjugates can be inexpensively prepared, are stable for 6 months, and have reasonably good sensitivity in most applications. The use of microtiter plates and instrumentation for dispensing reagents, wash procedures, and automated optical reading of reactions greatly facilitated EIA methods to allow large volumes to be batch tested (Fig. 10.18). However, some methods are time-consuming and may not be practical for low-volume laboratories or "stat" runs. They cannot always be considered rapid tests compared with other procedures such as LA. EIAs are used for rapid detection of *L. pneumophila*, *Clostridioides difficile* toxins, *G. duodenalis*, and *Cryptosporidium* spp. Because of low sensitivity, EIAs for *Chlamydia trachomatis* are considered substandard and are no longer recommended. Nucleic acid amplification tests (NAATs) are regarded as the tests of choice in clinical specimens.

Immunoassays for the detection of serum antibodies are performed in a manner similar to immunoassays for microbial antigen detection, except that the roles of antigen and antibody are reversed (Fig. 10.19). Most serum antibody assays are performed on a solid matrix using antigen-coated tubes or wells. Because of the large number of tests that can be performed and the small serum volume required, 96-well microtiter plates are commonly used for this purpose. Single-test, single-serum dilution cassettes are also available from commercial sources for settings with low-volume or infrequent testing. In either case, the patient antibody binds to the microbial antigen-coated surface, and the antibody is detected using an enzyme-labeled antihuman immunoglobulin, or conjugate. EIAs or, more specifically, solid-phase EIAs (enzyme-linked immunosorbent assay [ELISA]) are the most popular types of immunoassay in use today.

Many laboratories use some form of ELISA testing for antibody detection. In this test, results are reported not as antibody titer, but as the results relate to the relative amount of signal generated by the patient's serum compared with that of a known, weakly positive specimen. Results are usually reported as either relative units with a numeric reference range (U/mL) or as a ratio of results in the sample to the low positive control (e.g., patient 15 U/mL, control 10 U/mL, ratio 1.5). If the test result is above an established threshold,

Fig. 10.17 Principle of various enzyme immunoassays for antigen. Both methods (direct and indirect sandwich immunoassays) start with specific antibody bound to the solid phase. Arrows separate steps in the procedures where washing of the solid phase takes place. Y, Antibody; A-A, antigen; E, enzyme; enzyme substrate, enzyme product.

Fig. 10.19 Principle of indirect solid-phase enzyme immunoassay (EIA) for antibody detection.

the result is considered positive or reactive. It is impossible to compare the results of serial dilution methods with ELISA results because of the variation from test to test. However, there is a linear relationship in each individual assay between the amounts of antibody present, which means that a doubling in the EIA result yields a twofold increase in the antibody titer.

The *IgM antibody capture* ELISA specifically detects IgM antibody (Fig. 10.20). In this procedure, the solid phase is first coated with an animal antibody specific for human IgM. The patient's serum is added and incubated, and the tube or plate is washed. At this point, IgM antibody molecules, regardless of antigen specificity, should be bound to the solid phase, and antibodies of other immunoglobulin classes should be washed away. The next step in the assay involves adding the antigen of interest and can be performed in one of two ways. The antigen can be directly labeled with an enzyme or can be added unlabeled. In either case, the antigen will bind to the solid phase if the specific IgM antibody was present. With labeled antigen, the assay is completed by adding enzyme substrate and measuring the colored product. Alternatively, unlabeled antigen bound to IgM is detected by adding a secondary enzyme-labeled antibody directed against the specific antigen, followed by the addition of enzyme substrate. The amount of colored product is directly proportional to the amount of specific IgM captured on the solid phase.

Fig. 10.20 Immunoglobulin M (IgM) antibody capture enzyme-linked immunosorbent assay using labeled antigen (*left*) or unlabeled antigen; a secondary enzyme-labeled antibody is added later (*right*).

The IgM antibody capture assay has the advantage of eliminating the need for separation of IgG that might compete with IgM and yield false-negative results. The capture assay may be susceptible to false-positive results because of IgM RF bound to the solid phase. Modifications of the assay can be employed to reduce the possibility of this problem. Another way to distinguish between IgG and IgM is to use IgG-specific and IgM-specific conjugates.

A highly sensitive EIA variation utilizes **biotin-streptavidin systems**. Streptavidin can be linked to enzymes, often horseradish peroxidase, or fluorochromes such as fluorescein or rhodamine. Streptavidin is preferred over avidin because of greater sensitivity and a lower incidence of nonspecific binding. It binds very tightly and specifically to biotin by one of four reactive sites on each streptavidin molecule. When detecting an antigen in a clinical specimen, the antibody directed against the antigen is biotinylated. A specimen from the patient is fixed to a solid surface, and the biotinylated antibody is added. Following a wash step, streptavidin conjugated to an enzyme is added. After another wash step, the enzyme substrate is added, and a colored product is formed. The biotin-streptavidin interaction takes the place of the primary antibody–secondary antibody interaction. This assay

can be adapted for antibody detection by having the antigen attached to a solid surface, then adding patient sera. After washing, biotinylated antihuman antibody is added. This is followed by the addition of enzyme-labeled streptavidin as before. After this, the substrate is added. The biotin-streptavidin system increases the amount of signal detected (increased sensitivity) for the following reasons: (1) multiple biotin molecules can bind to the primary antibody and (2) each streptavidin molecule has four reactive sites for biotin. Biotin-streptavidin can also be used in competitive immunoassays.

Biotin-streptavidin assays have become very popular. A survey conducted in 2016 found that 59% of immunoassays (221/374) utilized this detection system. Because biotin (vitamin B7) is an essential nutrient, there are concerns that biotin in clinical specimens might interfere with these assays. Biotin in clinical samples could block the binding of biotinylated antibodies to the biotin binding sites on the streptavidin, resulting in falsely decreased results. Not all assays are equally affected by biotin, and it is likely that interference will only occur in patients taking biotin supplements. In these patients, laboratories should absorb biotin from clinical specimens with a pretreatment step using streptavidin microparticles.

Membrane-bound immunoassays

The flow-through and large surface area characteristics of nitrocellulose, nylon, and other membranes enhance the speed and sensitivity of EIA reactions. The improvements associated with membrane-bound EIAs are largely the result of immobilizing the antibody onto the surface of porous membranes. These assays use a disposable plastic cassette consisting of the antibody-bound membrane and a small chamber to which the antigen-containing clinical sample is added (Fig. 10.21). An absorbent material is placed below the membrane to pull, or wick, the liquid reactants through the membrane; this helps separate nonreacted components from the antigen-antibody

Fig. 10.21 TestPack Strep A kit components of membrane-bound enzyme immunoassay test for group A streptococcal polysaccharide antigen. (Courtesy Inverness Medical Professional Diagnostics–BioStar, Louisville, CO.)

complexes of interest that are bound to the membrane and simplifies the washing steps. Incubation times are also decreased because the rate of antigen binding is proportional to its concentration in solution near the membrane surface; this action increases the rate and extent of binding. Membrane-bound EIA tests are commonly used for the rapid antigen detection of rotavirus, RSV, influenza A and B viruses, *C. difficile* toxins, and group A streptococci (Fig. 10.22).

Lateral flow immunoassays, also called *immunochromatographic tests* (ICTs), are based on a similar principle. This assay can be used to detect an antibody or antigen. To detect an antigen in a clinical specimen, a capture antibody with specificity for the antigen in question is applied in a line (called the *sample* or *test line*) onto the membrane. Beyond the test line, a line of antirabbit antibody (control line) is attached. Below the test line on the membrane is rabbit antibody with specificity for the antigen in question labeled with a dye or colloidal gold. The clinical specimen is placed in a buffer diluent, and the processed specimen is added to the membrane. The buffer is carried laterally along the membrane by capillary action. The labeled rabbit antibody becomes suspended in the buffer, and if antigen is present in the clinical specimen, it forms a complex with the labeled antibody.

As the buffer migrates carrying the reactants, the antigen-antibody complex binds to the capture antibody affixed to the membrane at the test line. Enough of the complex binds to form a visible color, from the dye, on the test line. The control line is an internal control that must be positive for results to be valid. The control line captures any labeled rabbit antibody and is positive in specimens with or without the antigen. The control line ensures that the buffer has migrated past the test line and confirms a negative test result. This is the method used in home test kits for detecting severe acute respiratory syndrome coronavirus 2 antigen.

In an ICT assay to detect an antibody, such as anti-HIV (OraQuick; OraSure Technologies, Bethlehem, PA),

Fig. 10.22 Color PAC devices showing negative (A) and positive (B) reactions of liposome-enhanced membrane-bound enzyme immunoassay for group A streptococcal polysaccharide antigen. (Courtesy Becton, Dickinson and Company, Sparks, MD.)

staphylococcal protein A labeled with colloidal gold in the kit binds to the Fc portion of IgG with any specificity in the clinical specimen. The complex is carried to the test line, which contains HIV antigens. If anti-HIV antibody is present in the clinical specimen, it binds to the antigens and a red line develops. The control line contains antihuman antibody that binds IgG molecules not specific for the HIV antigen present in the specimen, producing a red line (Fig. 10.23). Because of their ease of use and built-in control, ICT assays have become popular in physicians' offices. Kits are available to detect numerous substances, such as drugs, and are used as field tests in forensic science.

Optical immunoassays

Optical immunoassay (OIA) relies on the interaction of antigen-antibody complexes on inert surfaces. Specific antigen-antibody

Fig. 10.23 Immunochromatographic test. The OraQuick test is a rapid assay for the detection of antibody to human immunodeficiency virus types 1 and 2. Formation of a red line in the test area is a positive reaction.

interaction alters the thickness of the reactants on the test surface. Light reflecting off the surface film containing an antibody only is viewed as one color. However, when a specific antigen is bound to an antibody, it increases the thickness of the film. This increased thickness causes the surface to appear a different color to the naked eye. An OIA is available to detect group A streptococci in pediatric populations (Fig. 10.24). An OIA also has U.S. Food and Drug Administration (FDA) approval for the detection of influenza A virus. A point-of-care test for *Neisseria gonorrhoeae* (BioStar; Alere) reacted positively with 99.4% of *N. gonorrhoeae* isolates and was negative with 88.7% of nongonococcal *Neisseria* isolates.

Complement fixation test

CF tests are versatile assays that can be used for both antibody and antigen detection. They are broadly applicable for various infectious agents and have been used for many years, particularly for antibody detection. In clinical laboratories, CF tests have been largely replaced by more rapid and sensitive assays; however, they are still used in reference and public health laboratories for certain agents.

Although the serum complement protein system plays a vital role in many immunologic functions, it is beyond the scope of this chapter (see Chapter 2). The proteins involved in the complement system are usually found in an inactive form; however, once activated, the proteins become involved in an enzymatic cascade that involves production of proteins with various biological activities. Activation of complement occurs by the classic pathway when specific IgG or IgM antibody combines with antigen and exposes a complement-binding site on the antibody molecule. It is the cell-lysing ability of activated complement components that is important in CF tests.

The CF test requires both an indicator system and a test system (Fig. 10.25). The indicator system typically consists of a combination of sheep erythrocytes, rabbit antibody to sheep erythrocytes, and guinea pig complement. When these three components are present and active, the rabbit antibody first combines with the sheep erythrocytes, and complement is subsequently bound (fixed) to the antibody-antigen complex, resulting in activation of complement by the classic pathway;

Fig. 10.25 Principles of complement fixation (CF) test. RBCs, Red blood cells.

this results in lysis of the sheep erythrocytes. The test system consists of a mixture of known antigen and a patient's heat-inactivated serum that may or may not contain specific antibody to the antigen. Heating the patient sample is necessary to inactivate complement present in human sera.

The CF test is performed as a two-step procedure. The patient's serum is serially diluted in test tubes to determine a titer, and each dilution is mixed with a known amount of antigen (test system). A fixed amount of complement is added to each tube, and the mixture is incubated. Next, the sheep erythrocytes and rabbit antibody are added (indicator system) to each tube, and the tubes are incubated again. If the patient's serum had specific antibodies to the test antigen, complement would be fixed by the test system and would be unavailable to lyse the erythrocytes. Therefore no hemolysis is a positive result for the presence of an antigen-specific antibody. If the patient's serum did not have the specific antibody to the test antigen, complement would be fixed by the indicator system, resulting in erythrocyte lysis. The CF antibody titer is the highest dilution of patient serum resulting in 100% hemolysis. It is usually read spectrophotometrically.

Western blot

Although serologic test methods for detecting an antibody such as IFA assays and EIAs provide excellent sensitivity and specificity in most clinical applications, they are limited in their ability to resolve the complex antibody response occurring during many infectious diseases. Because most antigens used in these assays are crude microbial and viral extracts, a positive result may represent an antibody response to one or many antigens. The EIA test can be designed to detect antibody to numerous individual antigens, but this requires the expensive and labor-intensive process of purifying antigens and running multiple EIAs. As an alternative, the technique of Western blotting is used. This technique allows for characterization of multiple antibodies with different idiotypes

to an infectious agent by electrophoretic separation of the microbial or viral antigens and then transfer to a nitrocellulose membrane.

Western blotting was previously used to confirm antibodies to HIV type 1 (HIV-1) in patients whose sera had been repeatedly reactive in EIA tests. However, it has been shown that using Western blotting for confirmation of reactive initial immunoassay results can produce false-negative or indeterminate results early during HIV infection. In addition, because of cross-reactivity, false-positive results were reported in 46% to 85% of patients with HIV-2 infection. Western blotting is still considered a confirmation test performed only after a positive screening test for the diagnosis of Lyme disease.

In the Western blotting procedure, a crude antigen preparation (e.g., a partially purified virus preparation) is heated with a detergent such as sodium dodecyl sulfate (SDS). The SDS releases individual polypeptides from complex proteins. The polypeptides are separated according to their molecular weight by polyacrylamide gel electrophoresis with SDS (SDS-PAGE). The separated polypeptides form invisible protein "bands" in the gel. The protein bands are transferred to an inert filter membrane support, usually made of nitrocellulose. The nitrocellulose membrane is a solid matrix to which the separated protein antigens tightly adhere and on which an antibody-antigen reaction can occur and be visualized—similar to a microtitration plate well with an ELISA.

Many commercial kits for Western blotting contain nitrocellulose membrane strips on which the protein antigens of interest have already been electrophoretically separated. For analysis, the nitrocellulose membrane is immersed in a patient's serum sample (usually diluted) and allowed to incubate. Specific antibodies in the sample, if present, bind to unique epitopes in the protein bands. After incubation, the nitrocellulose membrane is thoroughly washed to remove unbound antibody, and a labeled antihuman immunoglobulin (secondary antibody) binds to the primary antibody on the membrane. The secondary antibody is commonly labeled with an enzyme or biotin. The visualization of an antigen-antibody reaction at any protein band is accomplished by the addition of enzyme substrate (or enzyme-labeled streptavidin followed by enzyme substrate) and a final wash (Fig. 10.26).

Western blotting has added a dimension of versatility and specificity to immunoassays. It has helped resolve false-positive EIA results caused by antibodies cross-reacting with other infectious agents, autoimmune disorders, and technical error. It has also helped dissect and analyze the antibody response to individual proteins in complex mixtures. Western blotting is a procedure that must be well controlled and interpreted using strict criteria. Antibodies detected by other methods may not be detected by Western blotting techniques because the polypeptide antigens used are not native, intact proteins (SDS treatment denatures the proteins), and some antigens may not be transferred to the membranes. Western blotting is a qualitative assay; antibody titers cannot be determined. Despite these drawbacks, Western blotting is expected to continue to play an important role in the immunoserology of select infectious agents.

Dot blot

Dot blots are like Western blots, except the protein antigens are not electrophoretically separated and transferred to a solid surface. Instead, the proteins are purified and directly applied

Fig. 10.26 Western blot for detection of antibody to HIV-1. Strips 1 and 4 are high-positive strips; strips 2 and 5 are low-positive; strips 3 and 6 are negative controls. Strips 7 to 13 and strip 16 are positive reactions of patient sera. Strips 14 and 15 are negative reactions of patient sera. (Courtesy bioMérieux, Durham, NC.)

(blotted) to specific locations on the solid surface. An example is the ImmunoDOT *Borrelia* for Lyme disease (GenBio, San Diego, CA). Whole borrelial antigen, used to screen for antibodies, and four purified or recombinant proteins (for specificity) are applied to a nitrocellulose filter strip along with a positive control. Patient serum is added to the strip, and if an antibody to any of the proteins is present, they bind. An enzyme-labeled antihuman antibody is added, followed by the enzyme's substrate to detect binding of the patient's antibody. The strips are read manually.

Other labeled immunoassays

Besides enzymes and fluorochromes, other labels can be used to detect in vitro antigen-antibody reactions, including **radioimmunoassay** (RIA) and **chemiluminescent immunoassay** (CLIA). The principles are like EIA except a label other than an enzyme is used. Radionucleotides (usually iodine 125 or carbon 14) are substituted for enzymes in RIA. Although RIA was once the key method for antigen detection of numerous infectious agents, especially HBV, it has largely been replaced by EIA, which does not require use of radioactive substances. The CLIA uses chemicals, such as luminol, acridium esters, and ruthenium derivatives, that emit light. A luminometer is required to read CLIAs.

Use of serologic testing in specific diseases

As the sensitivity, specificity, and ease of use improved, serologic tests became a mainstay in clinical laboratories. Manufacturers produce kits for screening large numbers of samples and kits for confirming positive or negative screening results. Screening tests are designed to detect many

individuals who have a particular disease. However, because of the high sensitivity, these tests are prone to false-positive results. Remember, as sensitivity increases (more true positives), specificity decreases (more false positives). Positive screening tests should be confirmed with a more specific confirmatory test. In addition, some kits are for single use and designed for low test volume, whereas other kits lend themselves to large-volume testing and can be automated. See [Table 10.1](#) for lists of commonly used and commercially available serologic tests to detect antibodies and the organisms identified. This section discusses important diseases diagnosed by antibody detection. The next section examines direct antigen detection in the diagnosis of infectious diseases.

Serologic testing for syphilis

Sexually transmitted diseases (STDs) are among the most common infectious diseases in the United States. The most common of these diseases are genital warts, chlamydia, and genital herpes; however, syphilis is one of the most dangerous if left untreated. *T. pallidum* subsp. *pallidum*, the spirochete that causes syphilis, can be identified from a lesion or chancre. However, serologic testing for syphilis is the most common method of diagnosis. Two forms of testing exist for syphilis: screening tests and confirmatory tests. Screening tests generally do not use bacterial antigens and are referred to as *nontreponemal tests*.

The confirmatory tests use treponemal antigens and are very sensitive and specific, but they are not suited for testing large numbers of individuals (screening) because they are technically demanding and time-consuming, and like other diagnostic tests, they would result in decreased diagnostic accuracy if applied to a large population with a disease of low prevalence. Approximately 1% of the population would give a false-positive result. Confirmatory tests also cannot be used to monitor therapy. The four FDA-approved treponemal assays are the FTA-ABS test, the Serodia TP-PA (*T. pallidum* particle agglutination) test (Fujirebio America, Fairfield, NJ), the *T. pallidum* hemagglutination (TPHA) assay, and the microhemagglutination-*T. pallidum* (MHA-TP) test. In the TPHA and MHA-TP tests, specific treponemal antibodies are detected using treponemal antigen-coated erythrocytes (fowl for TPHA and sheep for MHA-TP). Because of ease of use, less technical time, and lack of an absorption step and fluorescent microscope, the TP-PA test is the most used confirmatory assay.

Nontreponemal antigen tests are technically easier and more rapid to perform, and they are the tests of choice for syphilis screening. The most used nontreponemal tests today are the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR) tests. The third FDA-approved assay is the toluidine red unheated serum test (TRUST). The VDRL test, named after the laboratory that developed it, is a microscopic flocculation test using heat-inactivated serum and performed on glass slides. The test detects reaginic antibodies (reagin) that bind to an alcoholic solution of precisely defined cardiolipin-lecithin-cholesterol particles. During the infection, these compounds are released from damaged host cells, resulting in antibodies being directed against them. Because nontreponemal antigens are used, the test is less specific than those assays using treponemal antigens. False positives have been associated with pregnancy,

Fig. 10.27 Rapid plasma reagin (RPR) card test for detection of nontreponemal antibodies. (Courtesy Baxter U.S. Distribution, Division of Baxter Healthcare, Deerfield, IL.)

intravenous drug use, and diseases such as systemic lupus erythematosus, mononucleosis, malaria, tuberculosis, and AIDS.

The RPR test uses the same antigen as the VDRL test; however, carbon particles have been added so the flocculation reaction can be seen more clearly. The RPR assay can be performed on unheated serum or plasma and is a flocculation reaction read macroscopically (Fig. 10.27). The TRUST resembles the RPR assay, except the dye toluidine red is substituted for charcoal. The VDRL and RPR tests and the TRUST detect both IgM and IgG and may be performed as both qualitative and semiquantitative tests. Because of the extreme attention to reagent preparation and quality control required and the difficulty in reading results, the VDRL test has been replaced by the RPR test in most clinical laboratories. However, the VDRL assay can be used to test CSF for diagnosing neurosyphilis and to follow antibody titers in a newborn to diagnose congenital syphilis. The RPR test can be used on CSF as well. However, its sensitivity is only 58% compared with 67% for the VDRL test.

Serologic testing for streptococcal infections

S. pyogenes causes many common, acute, pyogenic (associated with pus or neutrophil response) infections, including pharyngitis and skin infections. In addition, the organism is responsible for certain nonsuppurative (nonpyogenic) diseases, such as acute rheumatic fever and poststreptococcal glomerulonephritis, which occur weeks after the acute infectious process and are thought to be autoimmune-mediated diseases; that is, the damage is caused by the host's immune response. Although pyogenic infections are best diagnosed by isolation of the organism in culture, nonsuppurative diseases occur at a time when the organism may no longer be present; thus serologic diagnosis is often performed. In addition, it may be necessary to diagnose infections by serology after antimicrobial therapy has been initiated.

The ASO antibody test is used to demonstrate serologic response to *S. pyogenes*. One method to detect ASO is to measure the ability of the patient's serum to neutralize the hemolytic ability of the streptococcal enzyme, streptolysin O. The patient's serum is mixed with a standard concentration of streptolysin O. If antibody to streptolysin O is present, it binds to the hemolysin neutralizing it. When red blood cells

(RBCs) are added, the RBCs are not lysed. If antibody to streptolysin O is not present in the serum sample, the hemolysin is not neutralized, and the RBCs are lysed.

Antibody titers are based on comparison of the patient sample with known standards. Antibody titers are reported as Todd units, which are named after E. W. Todd, who discovered streptolysins. A fourfold increase in titer is considered diagnostic for a previous *S. pyogenes* infection. Titers peak 3 to 6 weeks after infection. High titers of ASO antibody develop in most cases of upper respiratory tract infection and rheumatic fever, but the titers and percentages of patients with streptococcal wound infections and poststreptococcal glomerulonephritis who develop ASO antibodies are significantly lower. Serologic assays to additional streptococcal antigens are discussed in Chapter 15.

Serologic diagnosis of viral diseases

Rubella

Rubella is normally insignificant, except in women who are pregnant. This disease may cause a miscarriage, or it may cause congenital heart disease, cataracts, deafness, or brain damage in the fetus. It is extremely important to determine whether women who may become pregnant have immunity to rubella. Serologic testing is generally by EIA for either IgM or IgG antirubella antibodies. Women who are not immune or have a low antibody titer should be vaccinated before becoming pregnant. Rubella vaccine is part of the trivalent measles, mumps, and rubella vaccine that most children in developed countries receive.

Infectious mononucleosis

The heterophile antibody titer is one of the tests used to diagnose infectious mononucleosis caused by EBV. The term *heterophile antibody* refers to an antibody with an affinity to an antigen from more than one group or species. Humans rarely have antibodies to sheep RBCs. However, many patients with infectious mononucleosis have been shown to develop antibodies that agglutinate sheep, bovine, and horse RBCs. Commercial diagnostic kits are available to help diagnose infectious mononucleosis. These kits are generally known as *spot tests*, and some use a saline suspension of antigen derived from the RBCs of horses (e.g., BBL MonoSlide). If the patient has infectious mononucleosis, mixing of the test reagent with a drop of the patient's serum causes hemagglutination. Some diagnostic kits place EBV antigens on carrier particles—RBCs or latex beads. Either IgM or IgG antibodies can be identified by these methods. These tests are rapid and sensitive for screening; however, they do not positively identify EBV infection. Because EBV antigens are not used, other factors may increase heterophile antibody titers; therefore the test is not specific. Other tests, such as antibodies to the viral capsid antigen and the Epstein-Barr nuclear antigen, are often needed to confirm active infectious mononucleosis.

Hepatitis

Hepatitis refers to inflammation of the liver. Many chemicals and infectious agents can cause hepatitis; however, most

cases of hepatitis have a viral etiology. Whereas several different viruses have been linked to hepatitis, hepatitis A virus (HAV), HBV, and HCV are the most common causes. Because of the extreme difficulty of isolating viruses causing hepatitis, serologic assays are very important for the diagnosis of viral hepatitis.

Numerous HBV serologic markers, both antibodies and antigens, are present in patients' sera soon after onset of infection. Serologic assays are often performed as a profile or panel of tests. One of the earliest markers detected in infections is the hepatitis B surface antigen (HBsAg). Although the virus has numerous antigens, HBsAg is highly antigenic and easy to detect. Additional antigen assays include detection of hepatitis B core antigen (HBcAg) and hepatitis B e antigen (HBeAg). The detection of HBsAg in serum signifies that the patient is either ill with the disease or is a carrier and is potentially infectious. The laboratory can also test for antibodies to the various antigens: anti-HBsAg antibody, anti-HBcAg antibody, and anti-HBeAg antibody. The presence of anti-HBsAg indicates immunity. A more thorough discussion of HBV serology is found in Chapter 29. HBV is spread in human blood, and blood units are screened for this virus to reduce the risk of posttransfusion hepatitis.

The tests most often used for the diagnosis of HAV infection are anti-HAV IgM and anti-HAV IgG. A positive anti-HAV IgM test is suggestive of acute infection, whereas a positive anti-HAV IgG test is indicative of past exposure. In the 1980s, a gene associated with an HCV protein was cloned. This protein was used to develop a test to detect antibodies to HCV in the blood. This was the first time a viral genome was used to develop a serologic test without first isolating the causative agent. Research determined that the primary agent in non-A, non-B transfusion hepatitis is HCV. Because HCV is found in human blood, blood units are screened for HCV with multiantigen assays detecting antibodies and with NAATs (see [Chapter 11](#)).

Case check 10.1

Based on the patient's clinical presentation and preliminary laboratory tests in the Case in Point, the physician suspected HIV infection. Laboratories generally screen for anti-HIV antibodies with an EIA. However, all reactive (positive) results must be confirmed by an additional serologic test.

Human immunodeficiency virus

The Centers for Disease Control and Prevention recommends that laboratories conduct initial testing for HIV with an antigen/antibody combination immunoassay that detects HIV-1 and HIV-2 antibodies and HIV-1 p24 antigen. Commercially available methods are based on EIAs and chemiluminescent immunoassays. Additional testing is not required for nonreactive specimens. However, a nonreactive result could occur early in the infection before antibodies were produced. Because antibody development in HIV infection has a wide variation depending on the patient, the infective dose, and the phenotype of the virus, seroconversion occurs an average 45 days after infection. For this reason, it is necessary to assay for HIV-specific proteins (antigens), such as p24 (a core protein)

or gp41 (a glycoprotein on the viral envelope). Screening kits detecting both the antibody and antigen, referred to as *fourth-generation tests*, are some of the most sensitive screening tests.

Specimens with a reactive antigen/antibody combination immunoassay result or a repeatedly reactive result must be tested with a supplemental immunoassay that differentiates HIV-1 antibodies from HIV-2 antibodies for confirmation. Supplemental assay methods include Western blot, indirect immunofluorescent assay, qualitative HIV-1 RNA assay, and HIV-1/HIV-2 antibody differentiation assay. The Western blot and indirect immunofluorescent assays detect HIV-1 infections later than other assay methods and therefore might produce false-negative or indeterminate results. The HIV-1 Western blot has also demonstrated cross-reactivity with HIV-2. For these reasons, the Western blot as a confirmatory test for HIV infection is falling into disuse. Specimens reactive on the initial antigen/antibody combination immunoassay and nonreactive or indeterminate on the individual HIV-1/HIV-2 antibody immunoassays should be tested with an HIV-1 NAAT. Assays vary in their sensitivity, specificity, and diagnostic utility and should be individually evaluated before use in a clinical laboratory.

The fourth-generation serology tests for HIV detect anti-HIV antibody and p24, the most abundant protein of HIV virions. Combining antigen detection with antibody detection increases the sensitivity of diagnosing a patient with HIV infection. Detection of p24 antigen is generally performed by capture EIA using a monoclonal antibody. One problem with this assay occurs during seroconversion. As the patient begins making antibodies to p24 antigen, immune complexes can form in vivo, which prevent the antigen and antibody from reacting with in vitro assays; this can result in false-negative results for both antigen and antibody detection assays.

Another problem with p24 antigen detection has been low sensitivity. Modification of the procedure, such as boiling the serum before testing to release immune complexes, has diminished the problem. However, their sensitivity remains less than that of NAATs. Blood units for transfusion are typically screened for antibodies to HIV, and a NAAT is performed for detecting viral RNA.

Case check 10.2

In the Case in Point, the patient's screening test for anti-HIV antibodies was reactive. Before a diagnosis of HIV infection can be assumed, a second confirmatory test must be performed. Previously, the Western blot assay was the confirmatory test most often used. Currently, the indirect immunofluorescent assay, qualitative HIV-1 RNA assay, or HIV-1/HIV-2 antibody differentiation assay are recommended.

Serologic diagnosis of fungal infections

Several methods have been used by clinical laboratories to identify antibodies in immunocompetent patients in response to fungal disease. Methods more commonly used today include ELISA, CF, immunodiffusion, and LA assay. The primary fungal diseases diagnosed by these means are histoplasmosis, coccidioidomycosis, and

paracoccidioidomycosis. Histoplasmosis is found primarily in the Ohio Valley. Coccidioidomycosis, or valley fever, is primarily seen in the San Joaquin Valley of California, and paracoccidioidomycosis is endemic from Mexico to Argentina. One fungal titer is not enough to be diagnostic because the people who live in an endemic area may have positive serologic tests from past exposure. A fourfold increase in titer is evidence of current infection. A travel history is mandatory when fungal disease is suspected.

The immunodiffusion and CF tests have been widely used for detecting antibodies during histoplasmosis. About 80% of patients will have a positive immunodiffusion test, and up to 95% will be positive by CF. However, the CF test is less specific because of cross-reactivity with aspergillosis, blastomycosis, tuberculosis, and other infections. The newer ELISA test has a reported sensitivity of 100% with acute disease and 90% in chronic disease.

The immunodiffusion assay for diagnosing coccidioidomycosis detects IgG and IgM. An ELISA is available that detects both IgM and IgG. IgM antibody is detected around the third week after infection; then the titer declines quickly. IgG antibody is detected in about 50% of infected patients by about 1 month. The test has been shown to have increased sensitivity, but there is concern about the test's specificity. It has been suggested that the EIA be used as a screening test and that any positive result be confirmed by a different method. LA assays are available from several manufacturers; however, the false-positive rate is higher than with other methods. Immunodiffusion and CF assays remain the most reliable. These two assays are also the most popular in diagnosing paracoccidioidomycosis.

Direct antigen detection assays

Antigen detection assays can provide rapid diagnosis of infectious agents, especially for those that are difficult or impossible to culture. Table 10.4 lists some infectious diseases that can be diagnosed by detecting antigens in clinical specimens. NAATs, discussed in Chapter 11, offer accurate, rapid results and are starting to replace direct antigen detection assays. As with any test procedure, laboratories must evaluate the tests for their situations.

Streptococcal pharyngitis

One of the most widely used applications of direct antigen tests, popularized in the 1980s, is for the detection of group A streptococci in throat swab specimens for the diagnosis of streptococcal pharyngitis. The main advantage of rapid direct antigen testing for streptococcal pharyngitis over a standard throat culture is that results are available while the patient is in the physician's office, allowing antimicrobial therapy to be given immediately instead of waiting 24 to 48 hours for culture results. This testing is more convenient for the physician and patient. Although antimicrobial treatment is critical for prevention of poststreptococcal pharyngitis syndromes, such as rheumatic fever and glomerulonephritis, early antimicrobial administration may also shorten the illness. In addition, early treatment may reduce secondary infections to close contacts, allowing the patient to return to school or work sooner. The most important reason for diagnosing

Table 10.4 Representative infectious diseases and direct antigen detection methods commercially available to detect them

Type of infection	Test methods
Bacterial	
Group A streptococcal pharyngitis	EIA, ICT, LA, liposome-enhanced immunoassay, OIA
<i>Clostridioides difficile</i> colitis	EIA, ICT
Legionnaires' disease	FA, ICT
Fungal	
Cryptococcal meningitis	EIA, ICT, LA
Pneumocystis pneumonia	FA
Parasitic	
Cryptosporidiosis	EIA, FA, ICT
Giardiasis	EIA, FA, ICT
<i>Trichomonas</i> vaginitis	ICT, FA
Viral	
Rotavirus gastroenteritis	EIA, LA
Hepatitis B infection	CIA, EIA
Respiratory virus infection ^a	EIA, FA, ICT
Herpes simplex virus infection	EIA, FA
Cytomegalovirus infection	FA
HIV infection	EIA

^aIncludes influenza, parainfluenza, and respiratory syncytial viruses.

CIA, Chemiluminescence; EIA, enzyme immunoassay; FA, fluorescent antibody test; HIV, human immunodeficiency virus; ICT, immunochromatographic test; LA, latex agglutination test; OIA, optical immunoassay.

and treating group A streptococci pharyngitis is to prevent the nonsuppurative sequelae. However, delay in initiation of therapy for a few days while awaiting culture results does not increase the patient's risk of developing such complications. Antimicrobial therapy begun as late as 9 days after the start of streptococcal pharyngitis will still prevent rheumatic fever.

More than 20 manufacturers produce diagnostic test kits for direct group A streptococcal antigen detection. These kits are based on immunoassays such as EIA and OIA. Generally, the tests contain reagents to perform an initial extraction of the group A carbohydrate antigen from the cell wall of the organism. This extraction is most commonly achieved by exposing the sample to nitrous acid, but it can be accomplished by enzymatic digestion (pronase). When the solubilized antigen preparation has been pH adjusted in a buffer, the specimen is tested according to the specific procedure of the manufacturer. EIA tests have become popular, particularly those that use membrane-bound antibody to speed up the reaction and facilitate the washing procedure. Because of the colored product, they are generally easier to read than LA tests. One variation of the membrane-bound EIA for group A streptococci uses colored, dye-filled liposomes bound to antibody as the detection reagent. These rapid tests are not as sensitive as culture, which remains the reference method. Rapid tests have a sensitivity of 80% to 90% in pediatric populations and about 90% in adult populations. Negative rapid tests in children and adolescents should be confirmed by throat culture.

Respiratory viral infections

Many respiratory viruses can be detected directly in both upper respiratory and lower respiratory tract specimens. The use of flocked swabs to collect upper respiratory tract specimens increases the quality and sensitivity of these assays. Flocked swabs have short, stiff nylon fibers extending from the shaft and act like a minibrush. Rapid techniques for detecting RSV, influenza A and B viruses, parainfluenza viruses 1, 2, and 3, and adenovirus include the immunofluorescent assay, immunochromatographic assay, and EIA. These assays may be used for direct detection or to confirm viral isolation in conventional cell culture tubes or shell vials. There is, however, great variability in the sensitivity and specificity of the tests. NAATs are gradually replacing antigen detection methods.

Of particular importance is the direct detection of RSV by fluorescent antibody or EIA and OIA in nasopharyngeal samples. The EIA and OIA are preferred over the DFA test because they are more rapid and less technically demanding. DFA tests have a reported sensitivity of 84% to 100% and a specificity of 86% to 100%. Rapid direct detection is important because RSV causes serious lower respiratory tract disease (bronchiolitis and pneumonia) in young children, often requiring hospitalization. Rapid results can help in making cohorting decisions on hospital admission. Also, it is difficult to maintain viral viability during transport; therefore it can be difficult to recover RSV in culture.

Influenza is another respiratory tract infection in which a rapid diagnosis is important for treatment. Many direct antigen tests with various formats are available for detecting influenza A or influenza A and B viruses. Generally, these tests have very good sensitivities and specificities, although sensitivity is lower in adults. Several formats are used including EIA, DFA, and ICT. Many assays require 2 hours and have sensitivities ranging from 50% to 80%. Several assays are characterized as rapid, providing results in 30 minutes or less, and are Clinical Laboratory Improvement Amendments waived. Two Clinical Laboratory Improvement Amendments-waived point-of-care tests are the QuickVue Influenza test (Quidel, San Diego, CA) and the FLU OIA (ThermoBioStar, Waltham, MA). These tests can be performed on numerous clinical specimens, such as nasal, nasopharyngeal, and throat swabs. Their sensitivity and specificity differ depending on the clinical specimen.

Bacterial meningitis

For years, clinical laboratories have regularly used antigen detection testing of CSF and other body fluids to detect organisms causing bacterial meningitis. Techniques have included EIA, coagglutination, and LA assays. The bacterial agents detected in commercially available kits include *H. influenzae* type b, *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *S. agalactiae* (group B *Streptococcus*). The sensitivities of many of these assays are very low, so routine use is no longer recommended. An exception is the Binax NOW *Streptococcus pneumoniae* Antigen Card (Alere). A study found that the ICT was positive for 68 (99%) of the 69 culture-confirmed pneumococcal meningitis cases and negative for 124 (99%) of 125 culture-confirmed meningitis cases caused by other bacteria. Multiplex polymerase chain

reaction (PCR) is generally considered more sensitive than culture and antigen detection.

The organisms causing meningitis often produce a bacteremia before invading the central nervous system. The organism and antigens may be detected in the serum before or at the same time as they are found in the CSF. Circulating organisms and soluble antigens are trapped, degraded, and released by phagocytic cells of the liver and spleen. These products are cleared from the body by filtration in the kidney and excreted in the urine; thus urine can be examined for the presence of antigens in addition to CSF in suspected cases of meningitis. Urine is also useful as a test specimen either alone or in addition to serum in cases of bacteremia and focal infections other than meningitis, such as pneumonia caused by *Legionella pneumophila*. Urine can be concentrated by ultrafiltration to increase test sensitivity.

The clinical utility of antigen tests for diagnosing meningitis varies with several factors including the manufacturer of the kit, the specific organism, and the type of specimen tested. In many clinical laboratories, the use of these tests is reserved for very specific diagnostic testing requirements. In most situations, Gram stain is sufficiently sensitive to detect bacterial meningitis. Gram stain of direct smears or antigen detection tests must always be performed along with culture. Most importantly, appropriate antimicrobial treatment should never be withheld pending culture results in patients with negative antigen test results, in contrast with the setting of antigen testing for group A streptococcal pharyngitis. The greatest clinical utility of these antigen tests is probably testing specimens from patients who have received antimicrobial therapy before cultures were collected and in whom Gram stained direct smear was negative. In this situation, the likelihood of recovering the organism in culture is dramatically decreased.

Giardiasis and cryptosporidiosis

The classic ova and parasite (O & P) diagnostic method requires chemical extraction, concentration, and microscopic examination of stool specimens. Although often considered the reference method, microscopic examination is technically demanding, is time-consuming, and requires trained personnel. Studies indicate, however, that the sensitivity of microscopic examination compared with immunoassays is low. In settings not including areas of endemicity for intestinal parasites (e.g., the United States), studies have suggested that 95% of all clinically important parasites detected in the United States are either *G. duodenalis* or *Cryptosporidium* spp. Several DFA, EIA, and ICT kits are available for detecting antigens from these parasites as well as *Entamoeba histolytica*/*Entamoeba dispar* directly from stool. DFA assays are performed on concentrated specimens, whereas EIA and ICT do not require concentration. Generally, the assays can be performed on fresh stool or stool preserved in 5% to 10% formalin or other preservative. Some formats include one monoclonal antibody to detect one organism; other formats use separate monoclonal antibodies for both organisms. When testing by DFA assays (see Fig. 10.13), the difference in size between these two parasites allows the laboratory scientist to distinguish the two organisms visually when using both antibodies in one procedure. Many laboratories offer these tests to screen immunocompetent outpatients.

Although the sensitivity and specificity of the immunoassays vary by manufacturer, these kits generally have sensitivities and specificities greater than 90%. However, studies found sensitivities of 68% to 75% in some ICT assays for *Cryptosporidium*. In addition, a high rate of false-positive *Cryptosporidium* rapid tests prompted laboratories to report positive test results as probable instead of confirmed.

A problem with antigen detection assays is that only two or three organisms can be detected; other clinically significant intestinal parasites would be missed that might have been detected with microscopic examination. Testing algorithms usually are established so only patients with a history of travel or immunosuppression require a full O & P workup when the screening test is negative. DFA assays also can be used to check municipal water supplies for *G. duodenalis* cysts; however, PCR assays are more sensitive and are used more frequently instead.

Case check 10.3

Although HIV infection is generally diagnosed by antibody detection, EIA for the viral p24 antigen is used to detect active viral replication in blood. Its greatest value is in the diagnosis of early infections, before antibodies are detectable, and in neonates in whom serologic diagnosis is of little value because of maternal anti-HIV IgG from a seropositive mother.

Infections in immunocompromised patients

Antibody detection in immunocompromised patients can be problematic because of the poor immune response in these patients. Direct antigen detection tests are sometimes more valuable. *Cryptococcus neoformans*, CMV, and *P. jirovecii* are important pulmonary pathogens in patients with transplants, cancer, and AIDS. Cryptococcosis is a devastating systemic infection generally limited to immunocompromised patients. Infection occurs initially in the lungs and rapidly disseminates to the brain and meninges. Before the advent of AIDS, disseminated cryptococcal infection was rare. Traditionally, the diagnosis of cryptococcosis meningitis has been based on culture of CSF or the presence of encapsulated yeast cells in India ink preparations of CSF. Antigen testing of CSF, performed by LA, EIA, or ICT, is considerably more sensitive than India ink direct examination of CSF. Antigen detection methods use polyclonal or monoclonal antibodies to the capsular (polysaccharide) antigen and are easy to perform. Quantitative antigen detection, which consists of titrating CSF antigens by performing serial dilutions, is an important prognostic indicator of clinical response to antifungal therapy. Many of these assays can be used on CSF and serum.

The Cryptococcal Antigen Latex Agglutination System (CALAS; Meridian Diagnostics, Cincinnati, OH) uses rabbit polyclonal IgG. This assay is more sensitive than assays using monoclonal antibodies. RF can produce false-positive results; therefore the manufacturer recommends pretreatment with pronase to remove RF and other nonspecific interference. The Remel *Cryptococcus* Antigen Test (Thermo Fisher Scientific, Waltham, MA) uses mouse monoclonal IgM; this assay incorporates a protease treatment for serum to prevent false-positive results by RF. The Premier Cryptococcal Antigen Test (Meridian Diagnostics) is an EIA that uses polyclonal antibodies attached to microwells. It has the advantage

Fig. 10.28 Bronchoalveolar lavage showing *Pneumocystis jirovecii* using fluorescent antibody test.

of fewer false-positive results, does not react with RF, and can be run on many samples at once. An ICT method, the IMMY Cryptococcal Antigen Lateral Flow Assay (CrAg LFA), manufactured by Immuno-Mycologics (Norman, OK), can be used on serum, urine, or CSF. It uses monoclonal antibodies directed against capsular material detecting all four serotypes of *C. neoformans* complex including *Cryptococcus gatii*. A meta-analysis of published data found a sensitivity and specificity of greater than 95% for serum and CSF.

Early CMV structural proteins can be monitored by the CMV antigenemia assay. In this procedure, buffy coats from whole-blood specimens are stained by fluorescent antibody, and the number of positive polymorphonuclear cells per cells counted is reported. Increased numbers of fluorescently stained polymorphonuclear nuclei are indicative of increased risk of developing CMV pneumonia or other end-stage organ disease. Antigenemia tests are important to determine CMV infection in solid organ and hematopoietic cell transplant patients.

A fluorescent antibody procedure for *P. jirovecii* is approved for use on induced sputum and bronchoscopy specimens (Fig. 10.28). The most sensitive kits are those with monoclonal antibodies directed against antigens found in all forms of the fungus. In patients with high probability of pneumocystis pneumonia, a negative fluorescent antibody test on induced sputum should be followed by a fluorescent antibody test on a bronchoscopically obtained specimen. *P. jirovecii* culture is not widely available, making fluorescent antibody assays the only reliable method for its detection in the clinical microbiology laboratory.

POINTS TO REMEMBER

- Although the words *antigen* and *immunogen* are sometimes used interchangeably, an immunogen is a molecule stimulating an immune response, whereas an antigen is a molecule capable of binding to a specific antibody or T-cell receptor.
- Using antibodies to diagnose a recent infectious disease requires either demonstrating a fourfold increase in titer between acute and convalescent samples or distinguishing between IgG and IgM.
- Although monoclonal antibodies have the advantage of being more specific than polyclonal antibodies in detecting antigens, polyclonal antibodies are more sensitive.

- False-negative tests for antibodies to specific antigens can occur if the serum sample is collected too soon in the course of the infection, the patient is immunocompromised, or antibody concentration is extremely high (prozone phenomenon).
- False-positive tests for an antibody can be caused by many situations, including the presence of heterophile antibodies or RF.
- Precipitation reactions are based on the insolubility of immune complexes formed after binding of soluble antigen to soluble antibody.
- Agglutination assays use particulate substances, such as latex, to form visible clumps to detect immune complexes.
- Antigens or antibodies can be labeled with numerous markers, such as fluorochromes or enzymes, to detect antigen-antibody binding in vitro.
- In syphilis serology, screening tests use nontreponemal antigens, whereas confirmatory tests use treponemal antigens.
- Direct antigen detection methods offer accurate, rapid alternatives to culturing infectious agents.
- Except for cryptococcosis, direct antigen detection in CSF is insensitive and not recommended.

LEARNING ASSESSMENT QUESTIONS

1. Serum is collected from a patient taking high doses of biotin supplement. The primary health care provider requested thyroid function tests, which are determined using biotin-streptavidin noncompetitive assays. Which effect might the biotin supplements have on test results?
 - a. Falsely decrease antibody concentration
 - b. Falsely increase antibody concentration
 - c. Decrease specificity
 - d. No effect on antibody concentration
2. What is the significance of a high titer of IgM to cytomegalovirus (CMV) in a neonate?
 - a. Likely a false-positive test result
 - b. Indicates past infection in the mother
 - c. Indicates maternal infection during pregnancy
 - d. Indicates that the mother received a CMV vaccination during pregnancy
3. Which of the following is an advantage of using monoclonal antibodies instead of polyclonal antibodies in immunoassays?
 - a. Increased sensitivity
 - b. Increased specificity
 - c. Decreased avidity
 - d. Assays can be performed more quickly
4. Serial twofold dilutions of a patient's serum sample are prepared. The dilutions are tested for the presence of antistreptolysin-O antibody in a neutralization assay. Dilutions 1:1 to 1:16 show no hemolysis, whereas dilutions 1:32 to 1:128 exhibit hemolysis. How should the results be reported?
 - a. 1 Todd unit
 - b. 16 Todd units
 - c. 32 Todd units
 - d. >128 Todd units
5. In the indirect immunofluorescent assay for detecting an antibody, what is the conjugate?
 - a. Antibody-antigen complex
 - b. Fluorochrome-labeled antigen
 - c. Fluorochrome-labeled antihuman antibody
 - d. Fluorochrome-labeled antibody directed against the antigen
6. Which advantage does the Western blot assay have over other serologic tests?
 - a. Distinguishes IgG from IgM
 - b. Can be a waived point-of-care test
 - c. Uses fluorochromes instead of enzymes
 - d. Determines the presence of antibodies to several different antigens
7. A patient's serum sample was reported as reactive in a rapid plasma reagin (RPR) test. What should be done next?
 - a. Repeat the RPR test.
 - b. Perform another nontreponemal antigen test.
 - c. Perform a confirmative treponemal antigen test.
 - d. Report as reactive; no additional action is required.
8. Which of the following antibody titer results is suggestive of an acute infection?
 - a. Single serum sample: IgG 4, IgM 32
 - b. Single serum sample: IgG 16, IgM 4
 - c. Acute sample: total antibody 128, convalescent total antibody 32
 - d. Acute sample: total antibody 64, convalescent total antibody 64
9. The presence of antibodies that agglutinate sheep and horse red blood cells is suggestive of which disease?
 - a. Syphilis
 - b. Strep throat
 - c. Lyme disease
 - d. Infectious mononucleosis
10. When performing a latex agglutination assay to detect an antigen, why do some kit manufacturers recommend diluting specimens that are negative and then retesting?
 - a. Excess antibody to the antigen could be providing a false-negative result.
 - b. Excess antigen could be providing a false-negative result.
 - c. High concentration of complement could be providing a false-negative result.
 - d. High heterophile antibody concentration could be providing a false-negative result.
11. How does double immunodiffusion differ from single radial immunodiffusion?
12. List some causes of false-negative serologic test results.
13. How does passive agglutination differ from reverse passive agglutination?
14. Explain why current screening tests for HIV infection include anti-HIV-1 antibodies, anti-HIV-2 antibodies, and p24 detection.

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the concept of nucleic acid hybridization and different parameters affecting the reactions.
2. Describe nucleic acid probes and how they are used for molecular diagnostic assays.
3. Explain the concept of nucleic acid amplification reactions and how these reactions are used in the clinical microbiology laboratory for molecular diagnostics.
4. Evaluate the use of nucleic acid amplification assays for molecular diagnostics.
5. Discuss the principle of the polymerase chain reaction (PCR) and the three types of PCRs.
6. Compare the methods of detecting PCR products.
7. Provide an overview of real-time PCR and the various real-time PCR detection methods.
8. Justify the uses of PCR in the clinical microbiology laboratory for molecular diagnostics.
9. Describe different amplification-independent procedures and how they are used in the clinical microbiology laboratory for molecular diagnostics.
10. Compare various strain-typing methodologies.
11. Discuss sequencing techniques, large-scale genomics, nanotechnology, and proteomics assays and their uses in the clinical microbiology laboratory for molecular diagnostics.

KEY TERMS

Plasmid profile analysis

Plasmids	Ribonuclease H (RNase H)
Polymerase chain reaction (PCR)	Ribotyping
Primer annealing	Rolling circle amplification (RCA)
Primer extension	Sanger sequencing
Primer-dimers	Scorpion primers
Primers	Sequencing
Probe	Southern blot
Proteomics	Strand displacement amplification (SDA)
Pulsed-field gel electrophoresis (PFGE)	Stringency
Pyrosequencing	SYBR Green
Random amplified polymorphic DNA (RAPD)	Target
Real-time PCR	Template
Repetitive palindromic extragenic elements PCR (Rep-PCR)	Thermal cycler
Restriction enzyme	Transcript (messenger RNA)
Reverse transcription PCR (RT-PCR)	Transcription-mediated amplification (TMA)
	Uracil- <i>N</i> -glycosylase (UNG)

Case in point

A 26-year-old male patient noticed a small “pimple” on his right flank. Within a few days, the pimple developed into a boil (infection of a hair follicle). The area around the boil became inflamed; the skin was red, the boil began to swell, and the entire area was painful. Subsequently, he became nauseated, started vomiting, and had a low-grade fever. When he presented to the emergency department, he was ill enough to be admitted to the hospital.

The boil was drained, and the pus was sent to the microbiology laboratory. Gram-positive cocci in clusters were observed on a Gram stain of the purulent material. The following day, creamy white, β -hemolytic colonies were observed on sheep blood agar. The colonies were catalase-positive and positive by latex agglutination for coagulase. A preliminary report of “*Staphylococcus aureus* present, susceptibilities to follow” was entered into the hospital’s laboratory information system.

A real-time **polymerase chain reaction (PCR)** assay was run to determine whether the *S. aureus* isolate carried the *mecA* gene, the determinant of methicillin resistance in many staphylococci. In less than 2 hours, the real-time PCR assay determined that the patient’s isolate was positive for the *mecA* gene. An internal control for an *S. aureus*-specific gene was also used in the assay, confirming the identification of the isolate. The patient was treated with appropriate antimicrobial agents and recovered.

Issues to consider

After reading the patient’s case history, consider:

- The patient’s symptoms and presentation that may indicate the identity of the agent
- The use of rapid molecular diagnostic techniques that can aid in the identification of a causative agent and treatment of a disease
- The potential benefits to patient care and selection of a treatment plan that may result from using molecular diagnostic techniques
- The length of time that molecular diagnostic assays (on a scale of hours) took compared with conventional microbiological methods (on a scale of days)

Molecular diagnostics represents a significant advancement in the clinical microbiology laboratory over traditional cultures and is probably the fastest-growing sector in clinical laboratories. Molecular biology techniques aid in the diagnosis of infectious diseases and are widely used as testing and validating options by clinicians. This is primarily because of the high sensitivity and specificity of molecular diagnostic assays and their short turnaround time. It becomes particularly useful for agents that are difficult to culture or take a long time to grow on culture media. Molecular diagnostic assays provide clinicians with rapid answers for treatment options, thereby saving time in life-threatening infections. Many highly sensitive and specific, easy-to-use molecular assays have been approved by the U.S. Food and Drug Administration (FDA) and are on the market for use in diagnosing infectious diseases.

As the name suggests, molecular diagnostic assays detect the presence of molecules such as nucleic acids (i.e., deoxyribonucleic acid [DNA] and ribonucleic acid [RNA]) and proteins in clinical samples and culture isolates. The types of assays used in molecular diagnostics include amplification of nucleic acids, sequence-specific hybridizations, and other assays that can specifically identify the target molecule. This chapter discusses these molecular-based techniques and their applications in the modern clinical microbiology laboratory.

Nucleic acid hybridization techniques

Nucleic acid hybridization is a technique first described in 1961 by Marmur and Doty. Most molecular diagnostic testing procedures use the concept of nucleic acid hybridization. Conceptually, nucleic acid hybridization refers to the formation of hydrogen bonds between pairing nucleotides—adenine (A) with thymine/uracil (T/U) and guanine (G) with cytosine (C)—of single-stranded DNA and/or RNA molecules that are complementary to each other. Under the right conditions, this forms a stable, double-stranded nucleic acid molecule. The resulting double-stranded hybrids may be DNA:DNA, DNA:RNA, or RNA:RNA, as depicted in [Fig. 11.1](#). This hybridization process is also called *duplex formation*. This coupling of complementary single-stranded molecules is a key component for many of the tests discussed in this chapter, including blotting methods, the PCR assay, and other nucleic acid detection techniques.

C CAAAUAGCAUAAUUC

Fig. 11.1 Three different oligonucleotide hybrids. **A**, DNA:DNA hybrid. **B**, DNA:RNA hybrid. The *top* strand is DNA, and the *bottom* strand is RNA; note the *Us* instead of *Ts*. **C**, RNA:RNA hybrid.

The two single-stranded nucleic acid molecules used in hybridization techniques are referred to by different terms. One of the strands is known as the **target** or **template**. The target strand is the DNA or RNA sequence that will be identified by the molecular diagnostic method used. The target nucleic acid molecule typically is immobilized on a solid support medium or suspended in solution. The other strand involved in hybridization methods is called the **probe**. The probe is usually a single-stranded DNA or RNA **oligonucleotide** labeled with a reporter molecule that can be detected visually or by an instrument. In essence, the probe is used to detect the target nucleic acid molecule. In most currently used molecular-based methods, the probe is produced synthetically to detect a specific target nucleic acid sequence of a given pathogenic organism. Probes are used for the detection of microbial pathogens in many different types of samples. Apart from microbiological diagnosis, probes are also used for gene expression analysis, identification of gene rearrangements, detection of point mutations, and other alterations at the nucleic acid level. Probes are an integral part of commercially available molecular diagnostic kits.

Hybridization reaction variables

Several variables affect the outcome of a hybridization reaction. These variables include the temperature, nucleotide base composition of the probe, length of the probe, probe concentration, degree of complementarity between the target and the probe, ionic strength (salt concentration), and pH. When one or more of these variables is not optimized for a hybridization assay, the hybrids may not form efficiently.

Temperature

Temperature is a variable that is probably the most easily controlled during hybridization. The stability of a given hybrid can be calculated by determining its **melting temperature** (T_m). The T_m is the temperature at which 50% of hybrids have formed and 50% of the single-stranded nucleic acid molecules are still dissociated. Generally, the T_m is dependent on the nucleotide composition of the probe, particularly on the percentage of guanine (G) and cytosine (C) nucleotides in the probe. This is often referred to as the G + C composition, or G + C ratio, of the probe. The T_m is dependent on the G + C ratio because three hydrogen bonds form between G and C, instead of the two hydrogen bonds that form between adenine (A) and thymine (T); the G-C pair is more thermodynamically stable than the A-T pair. The following formula is used for calculation of T_m of a sequence:

$$T_m = 2 \times ([\text{number of (A + T)}]) + 4 \times ([\text{number of (G + C)}])$$

Length of probe

Another aspect that affects the T_m is the length of the probe; in general, the T_m is lower for a shorter probe. Hybridization reactions tend to occur more rapidly for shorter probes than for longer probes. However, if the probe is too short, it can hybridize nonspecifically to unintended targets. An optimal length of at least 18 to 20 bp is used for probes to obtain specific hybridization.

Probe concentration

The probe concentration also affects hybridization reactions. Higher probe concentrations typically lower the reaction time by saturating all available probe target sequences. However, excessive probe concentrations could also promote nonspecific binding of the probe to nontarget sequences. The use of 1 : 2 to 1 : 3 molar ratios of target and probe is often the starting concentration for an optimal hybridization reaction.

Degree of target and probe complementarity

The basis of hybridization assays relies on the specificity of nucleic acid binding reactions. Most assays utilize a probe that has an exact complementarity sequence to the target nucleic acid. Such probes should not bind to nucleic acids from different strains of microorganisms that possess slightly different target sequences through point mutations. This **stringency**, or strictness of binding, is modulated by altering the hybridization parameters. Under optimal conditions, exact matches between the probe and target will hybridize first, whereas mismatches form duplexes more slowly. Increasing the length of the probe and lowering the hybridization temperature allow mismatches to form duplexes more readily compared with shorter probes and higher annealing temperatures. High hybridization temperatures and short-length probes prohibit the mismatch formation and make the reactions more stringent.

Salt concentration

Optimal concentration of salts is needed to stabilize the duplexes in the reaction. The salt concentration (the ionic strength) can also affect the stringency of a given hybridization reaction. The rate of a hybridization reaction will increase as the salt concentration increases, up to a threshold; past a concentration of 1.2M NaCl, the rate of the reaction becomes constant.

pH

The pH affects the stability of double-stranded nucleic acid molecules in solution. An alkaline pH promotes dissociation of double-stranded molecules, whereas acidic pH solutions can depurinate probes and target nucleic acid molecules. Thus a neutral pH is preferable for most hybridization reactions. Most hybridization reactions are done in buffered solution at neutral pH to ensure that pH changes do not alter the desired outcome.

Probe selection

Selection of the proper probe for nucleic acid hybridization reactions is just as important as the hybridization reaction method itself. Essentially, the function of the probe is to form a duplex (hybrid) with every complementary sequence available in the hybridization reaction conditions being used. Probes may be DNA- or RNA-based, although most often DNA is preferred because of its high stability and low cost compared with RNA. Probes must be labeled so a detectable signal is obtained upon their binding to the target. Initially, nucleic acid probes were labeled with radioisotopes. The radiolabeled probe often had to be prepared by the user, and

success of a hybridization reaction depended on the efficient incorporation of the radionucleotide label into the probe. In addition, these probes posed a health risk during use and generated radioactive waste that required special disposable protocols. Radiolabeled probes have been replaced for the most part by nonisotopic labels, including chemiluminescent (light-emitting) molecules, enzymes, and fluorescent dyes. Generally, nonisotopic labels have resolution and sensitivity that approach, match, or even exceed those of radionucleotide labels, depending on the manufacturer and process used. Also, nonisotopic labels do not require special handling and specialized waste disposal.

A probe may be end-labeled or internally labeled. An end-labeled probe has the label attached to the 5' or 3' end of the nucleic acid sequence. A 5' end-labeled probe can be synthesized by transfer of the probe via a kinase reaction, whereas a 3' end-labeled probe can be synthesized by using a terminal transferase enzyme. An internally labeled probe has the label incorporated at multiple nucleotides along the length of the nucleic acid sequence. This is often achieved by using a nick translation reaction. In this reaction, a dsDNA sequence is treated with DNase I enzyme, which creates nicks in the sequence. DNA polymerase removes nucleotides from the nicked sites and then incorporates labeled nucleotides at the sites. Internally labeled probes can also be purchased from manufacturers.

Hybridization formats

Hybridization reactions can occur on a solid support mechanism, in situ, or in solution. Solid support hybridization reactions were invented first and are still used today mainly for research applications. The most current diagnostic assays utilize in-solution hybridization formats.

Solid support hybridization

In solid support hybridization, a technique often also called *blotting*, the target nucleic acid is transferred to

and immobilized on a membrane composed of nitrocellulose or nylon. The solid membrane is often pretreated to reduce nonspecific probe binding to the membrane itself. The labeled probe is then hybridized to the immobilized nucleic acid, and washing steps are used to remove the excess probe and clarify the signal. Detection is based on the type of probe used; colorimetric probes enable visual determination of positive and negative reactions or quantitative results with an instrument measuring color intensity, while chemiluminescent probes require a detection instrument (luminometer). The luminometer gives a reading in relative light units (RLUs). Two examples of solid support hybridization techniques are the Southern blot and northern blot.

Southern blot

The **Southern blot** is named after the scientist, Edwin Southern, who developed this technique in 1975. In this technique, chromosomal DNA is separated by **agarose gel electrophoresis** and then transferred to and immobilized on a nitrocellulose membrane. Usually, this method is used after chromosomal DNA has been digested with a **restriction enzyme**, creating double-strand cuts in the DNA at specific nucleotide sequences. The DNA is first digested because chromosomal DNA is too large to separate in an agarose gel. Once the fragmented DNA has been separated and immobilized on a solid membrane, the membrane is incubated with a labeled probe that is specific for the target DNA sequence. The labeled probe hybridizes to the specific target DNA sequence and is detected, as depicted in Fig. 11.2. Southern blotting can be used to identify microorganisms, detect mutations, and type strains for epidemiologic investigations and for other purposes. Southern blotting is somewhat labor-intensive, often takes more than 1 day to perform, and is now rarely used in clinical microbiology laboratories.

Fig. 11.2 Southern blot. **A**, Chromosomal DNA fragments separated in an agarose gel are transferred to a solid membrane. **B**, A labeled probe specific for a nucleic acid target is incubated with the separated DNA on the membrane. **C**, Excess probe is washed from the membrane, leaving the probe bound only to the appropriate target DNA. **D**, The probe–target DNA hybrid is detected.

Northern blot

The **northern blot** is used to detect RNA molecules employing the same principle as the Southern blot. The procedure to blot RNA onto a solid support mechanism was first described by Alwine and colleagues in 1977. This technique was named to be in sync with the previously established Southern blot (not named after a person). Northern blots can be used to determine the size of RNA molecules and semi-quantitate the amount of a particular RNA transcript. Just like Southern blotting, RNA molecules are separated in an agarose gel, transferred to a membrane, immobilized, and detected with a probe that hybridizes to the RNA species (nucleotide sequence) of interest. Detection is accomplished according to the type of label on the probe. One difference between Southern blotting and northern blotting is that a restriction enzyme is not used to digest the RNA before separation; RNA molecules are small enough to be separated efficiently by agarose gel electrophoresis. Like Southern blotting, northern blotting is also tedious and is rarely used in clinical microbiology laboratories.

In situ hybridization

In situ hybridization (ISH) was first described in 1969 by Pardue and Gall. In this hybridization method, DNA or RNA transcript can be detected directly inside cells and tissues with labeled probes, often fluorochromes or enzymes. The technique can be performed directly in tissue that has been embedded in paraffin. ISH can also detect nucleic acids in intact cells and chromosomal genetic material. In microbiology, ISH can be used to detect low levels of viruses in tissue specimens, such as human papillomavirus (HPV). Some laboratories will couple an amplification procedure such as PCR with ISH to increase sensitivity and specificity. This technique is called **in situ amplification** (ISA). Both ISH and ISA are highly sensitive and require technical expertise. These tests are not used routinely in clinical microbiology laboratories but are required when higher sensitivity is needed, such as in detection of trace amounts of viral genetic material in tissue specimens during early infection.

In-solution hybridization

In-solution hybridization, or liquid-phase hybridization, is the hybridization reaction most often used by clinical microbiology laboratories. Several manufacturers have developed useful assays that promote hybridization between a labeled probe and target nucleic acids in a liquid solution in tubes or in microtiter wells. Generally, detection methods for these commercial systems are chemiluminescence-based. Labeled probes are used during in-solution hybridization to confirm culture-based identification of bacteria and fungi and to rapidly identify pathogens.

Applications of nucleic acid hybridization techniques

Culture confirmation probe applications

The AccuProbe system by Hologic (Marlborough, MA) uses nucleic acid hybridization to confirm culture isolates

for several different organisms, including various mycobacteria, fungi, and bacteria. Regardless of the application, all AccuProbe tests use the same underlying principle. A single-stranded, chemiluminescent-labeled DNA probe is designed to hybridize to the target organism's ribosomal RNA (rRNA), forming a DNA:RNA duplex. A luminometer is used to detect these labeled duplexes. The RLU result for an unknown culture isolate is compared with a positive cutoff RLU value; any reading above the cutoff value is positive, and readings below are negative. The RLU cutoff value can change from one assay run to another. These assays can be performed on cultures obtained in solid or liquid media. The sensitivity and specificity for most of these assays approaches 100%, and most of these tests take about 1 hour to perform.

Probe-based assays that identify microorganisms directly from specimens

An example of a probe-based assay is the BD Affirm VPIII Test (BD Diagnostics, Sparks, MD) for patients with symptoms of vaginitis or bacterial vaginosis. The BD Affirm VPIII test detects *Candida* spp., *Gardnerella vaginalis*, and *Trichomonas vaginalis* in vaginal fluid specimens. This test uses a capture probe and a color development probe. Capture probes are attached to beads on a card; there is a separate bead for each organism.

Another example of a probe-based assay is the Accelerate PhenoTest BC Kit (Accelerate Diagnostics, Tucson, AZ). This test uses fluorescent in-situ hybridization (FISH) probes to directly identify six gram-positive bacteria, seven gram-negative bacteria, and two yeasts from positive blood cultures in about 90 minutes. This system combines antimicrobial susceptibility testing by bacterial growth to determine the minimal inhibitory concentration for several agents in about 7 hours.

Nucleic acid amplification procedures

Even though labeled probes can be used in nucleic acid hybridization assays to detect microorganisms in the clinical microbiology laboratory, they are not useful when the amount of target nucleic acid is low. There are three types of amplification assays: (1) target amplification in which the target molecule is amplified; (2) probe amplification in which the probe is amplified upon binding to the target; and (3) signal amplification in which the binding of the target and probe result in amplified signal generation.

Amplification procedures have many advantages over standard microbiological methods and over direct nucleic acid hybridization procedures. Many amplification assays combine rapid detection times with high sensitivity and specificity. In general, amplification assays are more sensitive than their nucleic acid hybridization counterparts because target nucleic acid sequences may not be present in high enough numbers to be detected by direct hybridization assays. In some cases, amplification tests can also be used to detect target nucleic acid in clinical specimens, and they present the advantage of speed over culture identification methods. Some amplification techniques also provide quantitative data and are useful to track the progress of a disease or provide the number of copies of microbial or viral nucleic acid present in a sample.

Disadvantages of amplification procedures include expense, the need for specialized testing and detection equipment, dedicated space to reduce contamination, and specially trained scientists. In addition, amplification procedures are highly targeted and specific, while culturing techniques allow growth of all organisms present in the sample. Sometimes, the high sensitivity of amplification methods leads to overdiagnosis as it can identify even trace amounts of residual nucleic acids of the pathogen after the infection has been eliminated. The most used amplification procedure by clinical laboratories is the PCR or some derivation of it. The PCR assay is based on target amplification. Other examples of amplification procedures include **nucleic acid sequence-based amplification** (NASBA), **transcription-mediated amplification** (TMA), **branched DNA (bDNA) assay**, and **hybrid capture**.

Polymerase chain reaction

The technique of synthesizing DNA was first described in 1971 by Kleppe and associates, although Mullis and others at Cetus Corporation in California developed PCR into its current application in the early 1980s. Mullis eventually received the Nobel Prize in Chemistry for PCR, and the advent of PCR initiated a revolution in molecular biology and several other fields, including microbiology. PCR is valuable because it is simple, sensitive, and powerful. PCR can amplify a single copy of target DNA into an exponential amount of nucleic acid product over the course of 25 to 40 reaction cycles.

As shown in Table 11.1, each cycle consists of three steps: (1) **denaturation** of target DNA; (2) **primer annealing** to the target sequence; and (3) **primer extension**. PCR requires several components, including an enzyme commonly called **DNA polymerase** (properly called *DNA-dependent DNA polymerase*), a buffer for the polymerase, **primers** (oligonucleotides that **anneal** specifically to target DNA and prime or start the synthesis of new DNA strands), magnesium ions (in the form of magnesium chloride, needed as a cofactor for DNA polymerase), equimolar concentration of four **deoxynucleotide triphosphates** (dNTPs—dA, dC, dG, and dT), and a source of template DNA (the target).

In the first step, the PCR reaction mixture is heated to separate the strands of target DNA. The reaction is then cooled so the primers anneal to the separated target DNA strands. After this, primer extension occurs, which synthesizes new strands of DNA. The cycle then begins again with heating to separate (melt) all of the strands of DNA (including the newly synthesized strands). The target DNA is exponentially amplified over multiple cycles (25 to 40) of these three reaction steps. Fig. 11.3 shows one cycle of PCR.

Table 11.1 Three steps in a polymerase chain reaction	
Step	Purpose
Denaturation	Separates double-stranded DNA
Primer annealing	Anneals primers to target DNA
Primer extension	Synthesizes new strands of DNA
DNA, Deoxyribonucleic acid.	

The original PCR method described was labor-intensive and used two separate heat blocks and the Klenow fragment from *Escherichia coli* as the DNA polymerase. Target DNA is denatured at temperatures higher than 90° C, so one heat block was set to 95° C. The other heat block was set to 30° C, the temperature at which the Klenow fragment from *E. coli* functioned best, to anneal the primers. The amplification reaction then proceeded by manual transfer of the reaction tube from heat block to heat block for several cycles; in addition, a new Klenow fragment had to be added after every cycle because it denatures at 95° C. In 1986, an instrument called the *thermal cycler* was developed; it is a heat block that cycles rapidly between temperatures so individual heat blocks are not required. In 1988 a heat-stable (thermostable) DNA polymerase from the thermophilic bacterium *Thermus aquaticus* was used in PCR. This was a major breakthrough in that the polymerase had to be included only at the beginning of the reaction and did not have to be added after every cycle. Several variations of standard PCR have been described, including **reverse transcription PCR** (RT-PCR), **multiplex PCR**, and **nested PCR**.

Fig. 11.3 One polymerase chain reaction cycle. **A**, Template DNA is denatured by heat to yield two single-stranded DNA strands. **B**, The temperature of the reaction is lowered, and the two single-stranded primers (primers 1 and 2, blue) anneal to the template DNA strands, DNA polymerase (blue spheres, Pol). **C**, The temperature of the assay is raised to 72° C, and DNA polymerase adds nucleotides to the primers to synthesize new double-stranded DNA molecules (new DNA, red) in the primer extension step. The new DNA is then used for the next cycle.

Case check 11.1

The Case in Point illustrates a common type of *Staphylococcus aureus* infection, a boil. Although rapid identification of infectious agents by the clinical microbiology laboratory is always important, it is even more important with *S. aureus* to determine whether or not a particular isolate is methicillin-resistant. Methicillin-resistant *S. aureus* isolates are more difficult to treat than methicillin-sensitive strains. One of the primary advantages of using a rapid molecular method such as PCR to determine methicillin resistance is the speed offered by PCR; an answer can be obtained with PCR in about 1 hour compared with about 24 hours for standard antimicrobial susceptibility tests.

Contamination prevention

Because PCR is so sensitive, small amounts of extracted nucleic acid or carryover amplicons from previous PCR assays can contaminate future PCR assays. This can result in false-positive results. Many laboratories use biological safety cabinets or dead-air boxes to set up molecular assays away from other clinical specimens. To prevent contamination, all equipment and work surfaces must be thoroughly cleaned with, at a minimum, 10% bleach or 70% alcohol or both before processing and after setting up an assay. Many laboratories clean equipment and work surfaces with products such as DNA Away (Thermo Fisher Scientific, Waltham, MA) to prevent carryover contamination from previous reaction products.

In addition, aerosol-resistant pipette tips should always be used for all amplification procedures. It is important to always wear gloves and to frequently change them. Dedicated laboratory coats should be used in each work area as well. All sample and reagent tubes should be capped when they are not being handled. Some laboratories take routine samples from workspaces and equipment to determine contamination (wipe tests). Such contamination screenings should be adopted into the laboratory's quality assurance program. The samples are used as a template in PCR assays; screening can occur at a rate determined by the laboratory (e.g., on a quarterly basis).

Polymerase chain reaction product analysis

Analysis of PCR amplicons can be accomplished by different procedures. In the past, analysis by agarose gel electrophoresis with ethidium bromide staining was popular. Agarose gel electrophoresis takes 1 to 2 hours to separate PCR products, generates hazardous waste (e.g., ethidium bromide), and requires electrophoresis apparatus (Fig. 11.4) and an imaging system. Although agarose gel electrophoresis is still important in research laboratories, nearly all PCR assays used in clinical microbiology laboratories use **real-time PCR** to analyze PCR products.

Real-time polymerase chain reaction

Real-time PCR was a major breakthrough for the detection of PCR products. The method was developed in the early 1990s by Higuchi and coworkers. Amplicons are detected as they accumulate in real time after each PCR cycle. This is accomplished by increase in a readable fluorescent signal

Fig. 11.4 Agarose gel electrophoresis. An agarose gel is shown submerged in running buffer in a gel box; next to the gel box is a voltage source that supplies the electric current to separate nucleic acids. The blue loading dye is visible in individual samples and permits visualization of the samples as they migrate through the agarose gel matrix.

as the reaction proceeds. Therefore the PCR can be monitored as it happens as opposed to standard PCR using an agarose gel in which amplicons are detected at the end of the entire procedure. Real-time PCR does not require an agarose gel, it usually does not accumulate hazardous waste, and the imaging system is part of the real-time instrumentation. Another benefit to real-time PCR is that the reactions occur in closed tubes that do not have to be opened for detection. Thus there is a much smaller chance that an amplicon from a real-time PCR assay will contaminate equipment, reagents, and workspaces.

Another advantage is that real-time PCR is extremely rapid compared with standard PCR. Many real-time PCR assays yield positive results in 30 to 40 minutes compared with about 4 to 5 hours for standard PCR. For example, denaturation time for real-time PCR is usually a few seconds compared with 15 to 30 seconds for standard PCR. Also, many real-time PCR procedures use primers with a T_m of approximately 72° C, so annealing and primer extension occur at the same temperature. This saves considerable time. Real-time PCR can be used to quantitate nucleic acids, which is useful for monitoring the progress of certain infections, such as those caused by human immunodeficiency virus (HIV), hepatitis B virus, and hepatitis C virus. Nearly all commercially available PCR assays use real-time PCR for detection.

Real-time PCR uses a fluorescent reporter dye, often in the form of labeled probes or beacons, sometimes called a **fluorophore**; a thermal cycler that uses an ultraviolet light source to excite the reporter, and a camera controlled by a computer system. Real-time PCR instruments can measure increases in reporter fluorescence as PCR amplicons accumulate, leading to rapid, accurate results. Fluorescent peaks are recorded by the computer system as fluorescence intensity versus PCR cycle number. Fig. 11.5 shows a real-time PCR fluorescence curve.

Fluorescence is measured by directly monitoring an increase in fluorescence or indirectly by a process called **fluorescence resonance energy transfer** (FRET). FRET is the transfer of energy from a donor dye molecule to an acceptor dye molecule. FRET also occurs between a fluorescent dye and a quenching molecule that keeps emitted light low until

Fig. 11.5 Real-time polymerase chain reaction (PCR) data analysis for herpes simplex virus (HSV) from a human specimen. Fluorescent peaks are depicted as fluorescence intensity (*y*-axis) versus PCR cycle number (*x*-axis). An HSV-positive control (HSV PC) was assayed along with an internal control, β -actin positive control (β -actin PC), which should be present in all human samples. The HSV PC and β -actin PC have fluorescent peaks as does the β -actin assay from the unknown specimen, sample no template control (β -actin SNTC). The unknown specimen did not have a peak for HSV. In addition, a β -actin SNTC was assayed for both HSV and β -actin, and there were no fluorescent peaks for either one.

the fluorescent dye is released from the quencher. For FRET to occur, the two molecules must be in close proximity, within about one to five nucleotides of each other.

Some real-time PCR platforms can provide a **melting curve analysis** to determine assay results or verify the purity of the PCR product and determine whether primer-dimers are present. All dsDNA molecules have a T_m . This is determined by the length and GC content of the dsDNA hybrid. When a fluorescent dye is bound to the PCR product or attached to a probe bound to the PCR product, a fluorescent signal is detected by the real-time PCR platform. However, when the temperature is increased and reaches the T_m , the amount of fluorescence decreases as the probes and/or fluorescent dye dissociates from the PCR product. This decrease in fluorescence can be measured as a peak.

Real-time PCR platforms use different detection modalities, including the **5' nuclease assay** (sometimes called the *TaqMan assay*), **dual-probe FRET**, the **molecular beacons** probe, **Scorpion primers**, and intercalating dyes such as SYBR Green for detection of accumulated products. There are many commercially available real-time PCR platforms. A few examples include the 3M Integrated Cyclor (Focus Diagnostics, Fig. 11.6; now marketed by DiaSorin Saluggia, Italy, as the LIAISON MDX), the GeneXpert System (Cepheid, Sunnyvale, CA), the LightCycler 480 System (Roche Diagnostics, Indianapolis, IN), and the GeneAmp 9700 (Applied Biosystems, Pleasanton, CA). These platforms use rapid air exchange or rapid thermal conductivity around the reaction vessel to obtain rapid thermocycling; they also have a high surface-to-volume ratio of the PCR reagent mixture.

Fig. 11.6 3M Integrated Cyclor (Focus Diagnostics), another real-time polymerase chain reaction platform. (Image courtesy Steve D. Mahler.)

Case check 11.2

PCR can rapidly amplify the target sequence, but a decision must be made about which method will be used to determine how the amplicons generated are detected. Agarose gel electrophoresis allows the laboratory scientist to see stained amplicons, but this method adds another hour or more to the PCR process. Thus it is usually advantageous to use real-time PCR so amplicon-generated curves are displayed in real time. Results are generated more quickly with this method and can enable patients to be treated sooner.

5' nuclease assay (TaqMan)

The 5' nuclease assay uses the 5' exonuclease activity of some *Taq* polymerases (e.g., Gold DNA polymerase, Applied Biosystems) and TaqMan probes (Thermo Fisher Scientific). TaqMan probes are oligonucleotides about 18 to 22 bases long that are usually labeled on the 5' end with a fluorescent reporter dye and on the 3' end with a dye quencher. Fig. 11.7 illustrates the principle of a 5' nuclease assay. Fluorescence from the reporter dye is kept to a low background level because of the close proximity of the quencher by FRET (because of the conformation of the probe) in which the fluorophore donates energy to the quencher. The TaqMan probe for a specific PCR assay is designed to be complementary to a part of the internal region of the PCR amplicon during the primer-annealing step. During primer extension, the *Taq* DNA polymerase extends a complementary DNA strand from the primers using the template strand to which the TaqMan probe is annealed. The reporter dye is cleaved off by the 5' nuclease activity of the polymerase first, and then the entire probe is cleaved. Fluorescence increases as the fluorophore is removed from the immediate vicinity of the quencher. Fluorescence increases on a linear scale as more PCR product is synthesized during subsequent PCR cycles.

Advantages of the 5' nuclease method include (1) only specific PCR products are detected, (2) standard PCR protocols can be used, and (3) the hybridization and cleavage reactions do not interfere with production of the PCR product.

Fig. 11.7 5' nuclease assay (TaqMan). **A**, The primer and probe are annealed to the template DNA. DNA polymerase (P) starts to extend from the primer. **B**, DNA polymerase cleaves the fluorescent dye (F) from the probe and from the quencher (Q). Fluorescence is observed. **C**, As DNA polymerase continues to extend and synthesize a new strand of DNA, the probe is fragmented, and the fluorescent dye and quencher are fully released from each other. Fluorescence accumulates as fluorescent dye molecules are released.

One disadvantage is that specific probes must be designed and/or purchased for specific targets, and fluorescent-labeled probes are expensive compared with unlabeled oligonucleotides. Another disadvantage is that melting curve analysis cannot be performed when TaqMan probes are used because these probes are hydrolyzed during the amplification process.

Dual-probe fluorescence resonance energy transfer

This method is sometimes called the *dual-oligonucleotide FRET method* or simply the *FRET technique*. Dual-probe FRET uses two labeled probes, as shown in Fig. 11.8. One probe is labeled on the 3' end with a donor fluorescent dye, and the other probe is labeled at the 5' end with an acceptor fluorescent dye. The probes are designed to anneal head to tail to PCR amplicons. When this occurs, the two fluorescent dyes are brought into close proximity to each other, and FRET occurs. The light emitted by the real-time PCR platform excites the dye on the

Fig. 11.8 Dual-probe fluorescence resonance energy transfer. **A**, Two labeled probes anneal to the polymerase chain reaction product as it accumulates. One probe is labeled with a donor fluorescent dye (D) on the 3' end; the other probe is labeled with an acceptor dye (A) on the 5' end. The two probes anneal to the PCR product head to tail. A single strand of PCR product is shown in this diagram after denaturation has occurred. **B**, The light source from the real-time PCR platform excites the donor fluorescent dye. The donor then transfers this energy to the acceptor dye. The acceptor dye is excited and emits fluorescent light, which is read by the instrument. Fluorescence increases as the PCR product accumulates.

first probe, and this dye then gives off fluorescent light at a longer wavelength. The energy given off by the 3' dye then excites the fluorescent dye on the second probe because the two dyes are so close together. This dye then emits fluorescent light at a longer wavelength than before, and this is measured by the instrument. The intensity of fluorescent emitted light is proportional to the amount of PCR product amplified during the reaction. Emission is detected only when the two probes anneal to their respective complementary sequences on the PCR amplicons. It is important to note that detection of fluorescence occurs only after the two probes have hybridized, so measurement occurs during the primer-annealing step. When the temperature is raised for the primer extension step, the two probes are displaced by *Taq* DNA polymerase, and FRET stops because the probes are no longer in close proximity.

The next measurement is made after the primer-annealing step in the next cycle. This is a specific technique that also allows melting curve analysis of resulting PCR amplicons. However, the technique is expensive and requires probe design skill.

Molecular beacons

Molecular beacons use short segments of DNA with a fluorescent-labeled reporter dye attached to the 5' end of the DNA segment and a quencher attached to the 3' end (Fig. 11.9). The middle section (loop) of molecular beacons has about 20 bases that are complementary to the amplicon. The two ends are designed with complementary DNA bases so they can base-pair with each other and form a hairpin structure with a loop; fluorescence from the reporter dye is quenched by FRET while the molecular beacon is in the hairpin structure because the dye and quencher are in close proximity. As PCR proceeds, the denaturation step separates template DNA, PCR product DNA (if present), and the

Fig. 11.9 Molecular beacons. The molecular beacon probe is a complementary hairpin loop structure. A fluorescent dye is bound to the 5' end of the hairpin, and a quencher (Q) is attached to the 3' end. A loop structure at the top of the molecule is complementary to the polymerase chain reaction (PCR) product formed. When the denaturation step of PCR occurs, the PCR product and molecular beacon probes dissociate; a single strand of a PCR amplicon is shown here. The beacon anneals to the PCR product formed, and then the fluorescent dye is removed from the quencher molecule. Fluorescence increases as the PCR product accumulates.

molecular beacon. When the temperature is lowered for the primer-annealing step, the molecular beacon complementary DNA anneals to a PCR amplicon, opening the hairpin and moving the quencher and reporter dyes away from each other; hence the fluorescence from the reporter dye is emitted. Molecular beacons that do not find the complementary target form hairpin loops and do not yield any fluorescence signal. Fluorescence is observed in a linear fashion as PCR amplicons accumulate. During the next denaturation step, the molecular beacons leave the target strand and are available to bind to the newly formed templates in the next round of annealing. Unlike Taq man probes, molecular beacons get recycled and reused and can also be used for melt curve analysis of the PCR products.

Scorpion primer

A Scorpion primer uses a single oligonucleotide to prime a specific sequence and detect accumulation of PCR product. [Fig. 11.10](#) illustrates Scorpion primers and their mechanism. Structurally, Scorpion primers resemble molecular beacons in that the nonhybridized form of the Scorpion primer is a hairpin loop. Scorpion primers have a fluorophore probe with a PCR blocker linked to the 5' end and a quencher attached to the 3' end of the hairpin loop structure so fluorescence is quenched when target is not present. In addition, a stem on the 3' end of the hairpin loop is complementary to a specific sequence of the target DNA, which acts as a primer for the DNA polymerase, so the Scorpion primer is linked to the synthesized product at the end of the first round of PCR. At the start of the second cycle, the hairpin structure of the Scorpion primer denatures, along with the template DNA. The hairpin probe sequence then hybridizes to the product that was just

Fig. 11.10 Scorpion primer mechanism. **A**, A Scorpion primer is a probe and primer in one molecule. It is a hairpin molecule labeled on the 5' end with a fluorophore (F) and on the 3' end with a quencher (Q). A short priming sequence is also attached to the 3' end. The priming sequence anneals to the target DNA. **B**, DNA polymerase synthesizes a new strand of DNA from the short priming sequence. **C**, Denaturation occurs, and the newly formed DNA and Scorpion primer dissociate. An internal portion of the Scorpion primer is complementary to the product just formed. This portion anneals to the polymerase chain reaction product and separates the fluorophore from the quencher; fluorescence then accumulates.

synthesized. When this occurs, the fluorophore and quencher molecule become separated; accumulation of fluorescence indicates accumulation of PCR amplicons.

SYBR Green detection of real-time polymerase chain reaction products

SYBR Green is a fluorescent dye that binds to nucleic acids. SYBR Green I binds nonspecifically to dsDNA. The result of most real-time PCR applications is a dsDNA amplicon, so SYBR Green I is most often used in this application. Fluorescence increases as PCR product accumulates. SYBR Green I does not bind to denatured ssDNA strands at a high temperature. Some dye molecules begin binding to DNA during the primer-annealing phase, resulting in low-level background fluorescence. The dye then quickly binds to dsDNA during the primer extension step. As the cycles begin anew, fluorescence drops back to low background levels when the temperature is increased and denaturation occurs again. Thus detection by the real-time PCR platform occurs after every PCR cycle.

Using SYBR Green is less costly than using labeled probes, and it may be used for melting curve analysis. However, the dye binds to any nonspecific PCR products that form during assays and also binds to primer-dimers; thus it cannot distinguish among different PCR products. Note that melting curve analysis should be performed after SYBR Green detection is used to determine whether primer-dimers or nonspecific PCR products have formed. The melting curve temperature for primer-dimers and nonspecific products will be different than that for the amplified PCR products.

Other polymerase chain reaction procedures

Many different variants of PCR have been published in the literature or developed by various companies. Many of these PCR variations are used for specific purposes. Some of the more clinically used variant PCR procedures are discussed here, including reverse transcription PCR (RT-PCR), multiplex PCR, and nested PCR.

Reverse transcription polymerase chain reaction

RT-PCR uses an enzyme called *reverse transcriptase*, which is an RNA-dependent DNA polymerase, to synthesize a complementary strand of DNA (complementary DNA, or cDNA) from an RNA template. The resulting cDNA is then used as a template in a PCR assay using DNA polymerase (see earlier).

RT-PCR is often used in clinical microbiology laboratories to detect RNA viruses such as influenza virus and respiratory syncytial virus in clinical specimens. RT-PCR can be used to quantify the amount of virus in clinical specimens (e.g., HIV and hepatitis C virus). Other applications of RT-PCR include quantitative analysis of gene expression, detection of human genes involved in diseases, and detection of cancers in human specimens.

Multiplex polymerase chain reaction

Multiplex PCR is used to simultaneously detect two or more different targets in one sample in a single PCR reaction. In this technique, multiple primer sets for different targets are added together in the PCR reaction targeting different templates or different regions of the same template. Amplicon sizes from different genes should have a different length (base pair length) so distinct bands can be visualized by gel electrophoresis. Alternatively, distinct amplicons can be differentiated and visualized using primers coupled with different color fluorescent dyes.

Multiplex PCR can be broadly divided into (1) single-template PCR reactions that use a single template and several pairs of primers to amplify several regions within a template and (2) multiple template PCR reactions that use multiple templates and primers in the same reaction tubes. Most often, multiplex PCR is used to identify different species from a complex sample like contaminated water, food, or a clinical specimen. Several multiplex assays are available commercially to clinical laboratories for detection of multiple pathogens, mutant species, and viral variants.

Nested polymerase chain reaction

Nested PCR is a highly sensitive and specific PCR technique. Nested PCR consists of two different, consecutive PCR assays. The first reaction is a standard PCR assay using one set of primers. The amplicon produced from the first reaction

is then used as the target in a subsequent PCR assay. The second primer pair is complementary to an internal region of the amplicon derived from the first PCR assay. Amplicons are synthesized during this second PCR assay only if amplicons were produced from the first reaction, so this internal control mechanism serves as a marker of specificity.

Some clinical laboratories use nested PCR when the amount of starting template DNA is very low so the first reaction generates template DNA that is further amplified to a detectable amount. Also, some laboratories use a primer pair specific for a genus or viral family. If amplicons are present, as determined by agarose gel electrophoresis or real-time PCR, primers that determine species, strain, or type from a subsequent reaction are then used. For example, the first PCR assay could be used to ascertain whether a human herpesvirus is present in a sample. If present, primers specific for human herpesvirus type 1 and 2 could be used to determine the specific virus. One of the drawbacks to nested PCR is that it is not a closed system in that the first assay tube must be opened, so there is potential for contamination. Nested PCR is not used much in routine clinical microbiology laboratories.

Digital polymerase chain reaction

Digital PCR is a quantifiable, real-time PCR technique that translates exponential amplification data into digital signals. Digital PCR partitions a nucleic acid sample into many individual PCRs. In the newer digital PCR assays, called *droplet digital PCR assays*, the template and PCR reagents are dispersed into thousands of small droplets. Each droplet contains either only one starting target molecule or none, and a PCR reaction occurs in each droplet. Most of the droplets contain no template, and others contain individual target nucleic acid molecules. After multiple PCR amplification cycles, the samples are screened for fluorescence and recorded as 0 or 1. The fraction of fluorescing droplets is recorded. The absolute quantity of the nucleic acid can be determined by the count of positive signals (positive reactions). Reactions that have target nucleic acid are transformed into positive digital signals, and reactions with no target nucleic acid are transformed into negative digital signals. Digital PCR has been used in several applications, including genetic screening, oncology, and detecting low numbers of microorganism nucleic acid.

Applications of polymerase chain reaction in the clinical microbiology laboratory

With the commercial availability of real-time PCR platforms, many clinical laboratories use this method to diagnose bacterial, viral, fungal, or parasitic infections. Many assays have been described for antimicrobial drug resistance mechanisms as well. Several companies produce kit-based assays that are FDA approved for use in clinical laboratories. Some companies also produce kits called *analyte-specific reagents* (ASRs). ASRs are the active ingredients of an in-house test and are used by laboratories to establish and perform in-house (or so-called *home brew*) PCR tests. The manufacturer registers the product with the FDA, and laboratories use the ASRs in assays. Laboratories that use ASRs must establish and maintain performance of the PCR test and reagents. PCR assay patient results obtained with the use of ASRs can be reported

in a diagnostic setting. Laboratories that report results with ASRs must include a statement with the results, such as the following:

This assay and the test's performance characteristics were developed by [insert laboratory name]. This test has not been cleared or approved by the U.S. Food and Drug Administration (FDA). The FDA has determined that such clearance or approval is not necessary. This test is used for clinical purposes. It should not be regarded as investigational or for research. This laboratory is regulated under the Clinical Laboratory Improvement Amendments of 1988 (CLIA-88) as qualified to perform high-complexity clinical laboratory testing.

Several companies supply FDA-approved kits for their respective instrument systems for various organisms or antimicrobial-resistance genes. For example, Cepheid (Sunnyvale, CA) markets the GeneXpert system and offers PCR assays for various organisms including *Mycobacterium tuberculosis* that can be used directly on clinical specimens. Turnaround times are very rapid for these assays and can immensely improve patient care. Roche Diagnostics also offers various PCR assays on instrument systems. For example, the COBAS Amplicor is an automated PCR-based assay for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. The assay has FDA approval for testing endocervical swab specimens, urine from male patients, and urethral swab specimens from symptomatic male patients.

Other nucleic acid amplification reactions

Nucleic acid sequence–based amplification

NASBA is an isothermal procedure, which means that the reactions occur at a single temperature (usually 41° C), and therefore does not require a thermal cycler. NASBA is also referred to as *self-sustained sequence replications* (3SRs). The original method was described in 1989, but the method was not isothermal; instead, it used heat to denature the hybrids that formed during the procedure.

NASBA uses three enzymes: avian myeloblastosis virus (AMV) reverse transcriptase, **ribonuclease H** (RNase H), and T7 RNA polymerase. The amplification procedure results in multiple copies of RNA from the target sequence, as opposed to PCR, which results in multiple copies of DNA from the target sequence. The target nucleic acid can be DNA or RNA, although NASBA is most often used to detect RNA viruses such as HIV. During amplification, primers anneal to the target nucleic acid. One of the primers has a T7 RNA polymerase promoter added, and this primer initially anneals to the target sequence (Fig. 11.11). The reverse transcriptase generates a cDNA copy of the target, which results in a DNA:RNA hybrid. The enzyme RNase H then degrades the RNA, leaving the cDNA copy of the target; RNase H only degrades RNA from DNA:RNA hybrids. The second primer then anneals to the cDNA strand. Double-stranded DNA of

Fig. 11.11 Nucleic acid sequence–based amplification (NASBA). **A**, Primer 1 anneals to target RNA. **B**, Reverse transcriptase synthesizes a DNA copy of the RNA template. **C**, Ribonuclease H (RNase H) degrades the original RNA template. **D**, Primer 2 anneals to the DNA copy. **E**, Reverse transcriptase synthesizes another DNA strand, resulting in double-stranded DNA (dsDNA). **F**, T7 RNA polymerase synthesizes many copies of transcript using the dsDNA as a template. **G**, Primer 2 anneals to the synthesized transcripts. **H**, Reverse transcriptase makes a DNA copy of the transcripts. **I**, RNase H degrades the transcript copies, and primer 1 anneals to the DNA copies. **J**, Reverse transcriptase synthesizes new DNA strands, again resulting in dsDNA. **K**, The many copies of dsDNA are then used as a template by T7 RNA polymerase, which synthesizes even more transcript. This process continues in a loop.

the target is produced by the DNA-dependent DNA polymerase activity of AMV reverse transcriptase. The original primer with the T7 RNA polymerase promoter is integrated into this dsDNA copy of the original target nucleic acid. The T7 RNA polymerase then generates large amounts of transcript of the dsDNA. The transcript can be used again as a template for further amplification; instead, at this point, the second primer anneals to the generated transcript, and the DNA-dependent DNA polymerase activity of AMV reverse transcriptase once again makes a cDNA copy of these transcripts. The RNase H again degrades the RNA, and the first primer with the T7 RNA polymerase promoter anneals to the cDNA copies. The reverse transcriptase again synthesizes dsDNA, and the T7 RNA polymerase makes even more transcripts.

Thus amplification occurs continuously, and transcripts on the order of 10^9 are produced. The same method is used for DNA targets, although an initial denaturation step is required before NASBA can begin. NASBA is used to detect many types of viruses and microorganisms from clinical samples. The NucliSens EASYQ system (bioMérieux, Durham, NC) uses NASBA for the detection or quantification of viruses such as HIV-1 and HPV.

Transcription-mediated amplification

TMA, developed by Hologic, targets rRNA sequences of various microorganisms and produces large numbers of transcript using the same enzymatic processes as NASBA. The primary difference between the two methods is that TMA uses only two enzymes instead of three used in NASBA. In TMA, a reverse transcriptase with RNase H activity is used along with a T7 RNA polymerase to perform a reaction similar to the reaction in NASBA. The resulting amplified transcript is detected by Hologic's hybridization protection assay. Hologic Aptima assays utilize TMA on the Panther system. This automated system detects many different organisms, including *C. trachomatis*, *N. gonorrhoeae*, *T. vaginalis*, *Mycoplasma genitalium*, and herpes simplex viruses 1 and 2 from clinical specimens.

Strand displacement amplification

Strand displacement amplification (SDA) is an isothermal assay that can detect trace amounts of DNA or RNA. It can be used in multiplex reactions to detect several target sequences. The two phases of SDA are target generation and exponential target amplification. In the first phase, dsDNA is denatured and hybridized to two different primer pairs—the bumper and amplification primers. The bumper primers are shorter and anneal to the target DNA just upstream of the region to be amplified. The assay also utilizes a restriction enzyme and an exonuclease-deficient DNA polymerase. The primers bind followed by synthesis of dsDNA. The products then enter the second phase. The restriction enzyme nicks (makes a single-stranded cut) within the first primers. The polymerase then synthesizes a new strand, simultaneously displacing the original downstream strand, thus recreating the target sequence. The displaced strands can bind opposite strand primers, producing exponential amplification of the target sequences. Some of the single-stranded products bind to detector probes for real-time detection. The process continues amplifying the DNA. SDA has a reported sensitivity of as

few as 10 to 50 copies of target nucleic acid. It has been used to detect *M. tuberculosis*, *E. coli* O157:H7, and other infectious agents; hereditary diseases; and cancers.

Probe amplification reactions

These reactions amplify the labeled probe upon its binding to the target nucleic acid. Two types of probe amplification reactions include ligase chain reaction (LCR) and rolling circle amplification (RCA). The LCR is not used much today.

The RCA with padlock probes is an isothermal assay utilizing the ability of DNA polymerase to synthesize DNA on covalently closed circular templates to make a long linear strand containing multiple copies of a given sequence. RCA can replicate up to thousands of complementary amplicons into a single, long-stranded DNA. For probe amplification, the ligation of a padlock probe results in circularization of the target nucleic acid and thus triggering of an RCA reaction. Advantages of this method are resistance to many contaminants and excellent specificity. Disadvantages are the need for special instrumentation, and it is difficult to achieve quantitative detection. The padlock probe is used in diagnostic laboratories to detect several disease-related genes, Epstein-Barr virus (EBV) in human lymphoma specimens, influenza A H1N1 and H3N2 mutations, HIV, and more recently, novel coronavirus-2.

Signal amplification reactions

Several assays are currently used in clinical microbiology laboratories that exploit signal amplification for detection, rather than target or probe amplification. Signal amplification procedures used in clinical laboratories include bDNA detection, hybrid capture, and the Invader assay.

Branched DNA detection

Branched DNA (bDNA) detection is a sensitive signal amplification technique first described in 1991, and commercial assays are available for the quantification of RNA from hepatitis C virus and HIV and quantification of DNA from hepatitis B virus. This method uses oligonucleotide *capture probes* that hybridize target nucleic acid to a solid support mechanism, such as a microtiter tray (Fig. 11.12). Other probes, the *target probes*, anneal to a different region of the target nucleic acid than the capture probes. The target probes also hybridize to preamplifier probes. Amplifier probes then bind to the preamplifier probes, which forms a bDNA structure. Finally, probes labeled with alkaline phosphatase (AP) are added and hybridized to the complex; the complex is large, and many AP probes can hybridize to the bDNA structure.

When the AP substrate is added, chemiluminescence results, and light emission is detected by a luminometer and reported as RLUs. The amount of light signal is directly related to the amount of nucleic acid present in the sample. Standards are used with known concentrations of target nucleic acid, so a standard curve is established in light units during each bDNA assay. Unknown samples are compared with the standard curve to determine nucleic acid concentration. Although very strong signals are generated, there is an inherent risk of nonspecific results; therefore it is employed for quantitative viral loads in the clinical samples rather than for the detection of pathogens in the sample.

Fig. 11.12 Branched DNA (bDNA) detection. **A**, Capture probes attached to a surface anneal to target nucleic acid. **B**, Target probes anneal to nucleic acid and to preamplifier probes. **C**, Amplifier probes anneal to preamplifier probes, forming a bDNA structure. **D**, Label probes (with bound alkaline phosphatase [AP]) anneal to the bDNA structure. A large amplified signal is detected enzymatically when the AP substrate is added.

Hybrid capture

The hybrid capture method was developed by Digene in 1995 to detect HPV in clinical specimens. It is often done as in-solution hybridization. There are three steps: in the first step, the clinical samples are mixed with an alkaline denaturing solution that releases single-stranded viral nucleic acid into the solution. Then, an RNA probe specific for the target DNA is added to the sample, and a RNA:DNA hybrid forms (Fig. 11.13). A capture antibody is used to bind the hybrid onto the microtiter wells. Antibodies conjugated to AP are added to detect the captured hybrids. Multiple AP antibodies bind to each hybrid, resulting in signal amplification of approximately 3000-fold after a chemiluminescent substrate for AP is added. A luminometer reads light signals as RLUs. The initial assay, the Hybrid Capture I test, detected two HPV risk groups for cervical cancer: high-risk and low-risk HPV types. Testing was performed in tubes, and the method was a liquid hybridization assay. The Hybrid Capture II method (Qiagen, Frederick, MD) is automated and detects HPV types high risk for cervical cancer, *C. trachomatis*, and *N. gonorrhoeae*. A “detected” result for HPV does not identify which one of the high-risk 13 serotypes assayed for was detected. All three infectious agents can be detected from a single clinical sample in a microtiter plate format, and currently it is an FDA-approved assay for Pap smear specimens.

Fig. 11.13 Hybrid capture. **A**, RNA probes are annealed to target DNA, resulting in RNA:DNA hybrids. **B**, The hybrids are bound to capture antibodies attached to a solid support mechanism. **C**, Several alkaline phosphatase (AP)-antibodies bind to hybrids. The substrate is added for the AP and resulting light emission is captured by a luminometer.

Fig. 11.14 Invader technology. A primary oligo and the Invader oligo anneal to the target DNA sequence, creating an overlap. The enzyme cleavage acts on this overlap at the cleavage site, releasing the 5' flap from the primary oligo. This 5' flap anneals to a fluorescence resonance energy transfer (FRET) cassette. The cleavage enzyme then acts on this structure, releasing a probe that is then detected.

Invader assay

Invader technology (Hologic) uses two different oligonucleotides that anneal to target DNA (Fig. 11.14). One is the primary probe oligonucleotide, and the other is the invader oligonucleotide. The primary probe oligonucleotide has a

flap, or arm, on the 5' end. When these two oligonucleotides anneal to the target DNA, they overlap. This forms a structure that is recognized by the enzyme cleavase. The 5' flap is cleaved by this enzyme at the overlap position. This newly released 5' flap then anneals to a FRET oligonucleotide called the *FRET cassette*. This creates another invasive structure that cleavase will use as a substrate. The interaction of cleavase releases the fluorophore and yields a signal. The probes in the reaction mixture are present in molar excess, so many probe interactions and signal-release events occur if the correct target DNA sequence is present. Invader chemistry is used with the Cervista HPV assay (Hologic).

Strain typing and identification

With the rise in the number of antimicrobial-resistant microorganisms, increases in the rates of toxin-producing bacteria, and spread of pathogenic microbes worldwide, there is a need for accurate, rapid, epidemiologic surveillance of these organisms. Standard techniques in clinical microbiology laboratories do not often provide the necessary resolution to distinguish types and strains. Instead, more refined techniques that separate related organisms from each other at the genetic level are necessary for epidemiologic investigations. Many typing methods have been described to determine genetic relatedness among bacteria, fungi, and parasites, and some provide better resolution than others. These techniques, often called *DNA* or *genetic fingerprinting*, are based on mutations that accumulate in biological organisms over time.

Strain typing techniques are often used to compare strains to determine whether a local outbreak is caused by a single strain type or by multiple strains. A single strain that is responsible for a disease outbreak may have a point source that can be targeted by public health services. Strain typing methods are also used to compare local isolates with worldwide isolates, which can show long-term spread of a strain or strains (clonality).

Whether testing local isolates or isolates from many locales, the technique chosen should have high discriminatory power or the ability to finely resolve different strains. Genetic fingerprinting techniques involve both amplification-dependent and amplification-independent methods. Amplification-independent strain typing methods usually involve the analysis of restriction enzyme fragments of chromosomal DNA. As strains diverge genetically over time, restriction enzyme sites on the chromosomal DNA will change as point mutations accumulate. When chromosomal DNA from different strains is digested with one restriction enzyme and separated by agarose gel electrophoresis, fragments of different sizes will be observed. These fragments are referred to as *restriction fragment length polymorphisms* (RFLPs). Comparisons of these RFLP patterns lead to strain typing, and evolutionary ancestors can be derived from the RFLP patterns. Similar RFLP patterns imply genetic relatedness.

Other amplification-independent typing techniques include Southern blotting, **plasmid profile analysis**, **pulsed-field gel electrophoresis** (PFGE), and **multilocus enzyme electrophoresis** (MLEE). Amplification-dependent fingerprinting methods use PCR and its variants discussed earlier. Known primers or arbitrary primers are used, depending on the technique. Commonly used amplification-dependent

methods include arbitrarily primed PCR (AP-PCR), also called **random amplified polymorphic DNA** (RAPD), **repetitive palindromic extragenic elements PCR** (Rep-PCR), and **multilocus sequence typing** (MLST).

Amplification-independent methods for strain typing

Plasmid profile analysis

This technique was one of the first methods used to type bacterial strains. **Plasmids** are extrachromosomal, circular DNA molecules found in variable number in the cytoplasm of many bacteria. Many bacteria carry antimicrobial-resistance genes, virulence genes, and other targets of interest on plasmids. The theory behind this technique is that a given strain with a plasmid profile will be unique from other strains with other plasmids. When a plasmid profile of different isolates is the same, it is possible that these strains are from the same clone.

Plasmid DNA is extracted from bacteria and separated by agarose gel electrophoresis. Unfortunately, because plasmids are extrachromosomal genetic elements that do not code for essential products, they are readily lost. Some plasmids also contain transposons, or so-called *jumping genes*, that are readily transferred to other bacteria. In addition, plasmids can exist in different forms in bacterial cells. Plasmids that have been cut or nicked will have different sizes on agarose gels than uncut plasmids. All of these factors can readily change the plasmid profile of a given bacterial isolate; therefore this technique is not often used in clinical diagnostic laboratories because of a lack of reliable reproducibility.

Southern blotting

Southern blotting, as described earlier, is sometimes used in epidemiologic investigations to analyze RFLP patterns. Chromosomal DNA is digested with a restriction enzyme, and the resulting fragments are separated by agarose gel electrophoresis. These fragments are transferred from the agarose gel to a nylon or nitrocellulose membrane, and a labeled probe is used to identify a specific target. One of the most popular targets is the DNA gene that codes for rRNA. When rRNA RFLP patterns are detected by Southern blotting, the technique is called **ribotyping**. The genes that code for rRNA are conserved in different species of organisms and appear in conserved positions of a species chromosome. Therefore ribotyping displays excellent reproducibility and discriminatory power.

A fully automated ribotyping platform that uses Southern analysis methodology is the RiboPrinter System (Hygiena, Camarillo, CA). The instrument automates the entire process, including lysing cells and data processing. Unknown patterns are compared with known patterns to identify strains. Some reports have indicated that other methods, such as PFGE and RAPD, have greater discriminatory power than automated ribotyping. However, automated ribotyping is advantageous for high-volume laboratories that evaluate large numbers of isolates. Other targets for Southern blot analysis are insertion sequences and transposons, which often contain genes involved in virulence and antimicrobial resistance. However, insertion sequences are not present in all strains of bacteria, so some strains are nontypeable.

Restriction enzyme analysis of chromosomal DNA

This technique resembles Southern blotting. Chromosomal DNA is extracted from isolates of interest and digested with one or more restriction enzymes. The enzymes used for digestion should cut the chromosomal DNA in several places so small and large fragments are produced. The resulting fragments are separated by agarose gel electrophoresis and transferred to a membrane. A probe to identify a specific sequence is not used. Instead, the DNA fragments (RFLP pattern) are stained and compared. The discriminatory power of this method is not high, and many of the fragments overlap and are difficult to distinguish from each other.

Pulsed-field gel electrophoresis

Schwartz and Cantor developed PFGE in the early 1980s. The technique is extremely popular and is perhaps the most well-known epidemiologic investigation method. It is used for strain typing and identification. A restriction enzyme is used to digest chromosomal DNA at a small number of sites along the chromosome. This results in large DNA fragments that are difficult to resolve by standard agarose gel electrophoresis. During PFGE, these large fragments are separated in an agarose gel by an angled electric field that periodically changes orientation. These changes in electric field orientation are pulses that successfully force the large DNA fragments through the agarose gel and separate them by size. A low-percentage agarose gel is used for the large DNA fragments, and low-melt agarose enables large fragments to migrate more easily. Relatively simple RFLP patterns result from this process, so comparisons are usually easy.

PFGE is also very reproducible and can theoretically be used on any organism. Fig. 11.15 shows representative PFGE patterns from different *S. aureus* strains. Generally, special equipment that can provide electric pulses must be used specifically for PFGE. Most PFGE assays take several hours (up to overnight) to efficiently separate the large DNA fragments produced in the restriction enzyme reaction. Most PFGE systems incorporate a chilling module within the system to cool the electrophoresis buffer and circulate it to improve separation. Without circulation and a chilling unit, the buffer will become very warm when separation proceeds for several hours—warm enough to potentially degrade the low-melt agarose gels used in PFGE. The warm temperatures also could produce wavy and difficult-to-interpret RFLP patterns. Among the various PFGE systems available is the GenePath strain typing system (Bio-Rad, Hercules, CA).

Multilocus enzyme electrophoresis

Unlike the other typing techniques described in this section, MLEE analyzes gene expression polymorphism. Analysis of protein polymorphisms by electrophoresis has been studied since the 1970s. MLEE involves extraction of proteins from isolates of interest, followed by electrophoretic separation and selective staining of these proteins. The expression of the protein's genotype is reflected in the position of the stained band, according to the protein's mobility. Mobility is determined by the net charge and structure of the protein. Two bands of the same protein in different positions after separation suggest two different conformations of the protein, in other words two alleles of the same gene.

Fig. 11.15 Example of pulsed-field gel electrophoresis (PFGE) analysis of *Staphylococcus aureus* strains. Lanes 1 and 5, Known control strains of a *S. aureus* isolate. Lanes 2 to 4, Unknown strains from different patients with *S. aureus* isolates. Lanes 2 and 3 have the same banding pattern after PFGE and are the same strains. The lane 4 isolate is an unrelated strain.

MLEE is an excellent strain typing method. Unfortunately, the DNA sequence of the proteins separated during MLEE cannot be directly ascertained because different DNA sequences can result in the same protein because of the redundancy of the genetic code. In addition, two completely different proteins could have the same mobility and might be interpreted as the same proteins. Another problem is that interlaboratory comparisons are difficult. MLST, discussed later, was eventually developed because of these potential problems with MLEE (see later in this chapter).

Amplification-dependent methods for strain typing

Random amplified polymorphic DNA technique

The RAPD technique, also called *arbitrarily primed PCR*, was first described in 1990 by two different groups, Williams and colleagues and Welsh and McClelland. This is a popular method of DNA fingerprinting using small primers, approximately 10 nucleotides in length, with random sequences. These primers thus do not have a specific target. Instead, the random primers indiscriminately amplify chromosomal DNA during PCR cycles, which results in fragments of various lengths. After separation by agarose gel electrophoresis, different strains will have different fragmentation patterns.

The RAPD technique is a simple DNA fingerprinting method capable of providing high resolution. A single primer can be used in a RAPD PCR assay because the single random oligonucleotide can bind random targets on either strand of template DNA. However, the discriminatory power of just one primer is low. The discriminatory power increases if three or more primers are used, although this increases the assay time. Many laboratories use eight or more primers for RAPD DNA fingerprinting. One potential problem of the RAPD technique is interlaboratory agreement and reproducibility, although this method typically provides excellent intralaboratory reproducibility. RAPD analysis often yields some minor amplicons that exhibit low reproducibility in the same laboratory. Some researchers believe that PFGE has higher discriminatory power than RAPD analysis.

Repetitive palindromic extragenic elements polymerase chain reaction

The Rep-PCR technique is an amplification strain typing method first described in 1991 by Versalovic and associates. All organisms have repetitive DNA sequences—repetitive palindromic extragenic elements—that repeat throughout the genome. The unique DNA sequences that lie in between these palindromic repeats are amplified during Rep-PCR using primers specific for the repeat DNA. Rep-PCR results in fragments of various sizes, depending on the locations of the palindromic repeats. The length of DNA in between the repeats differs from strain to strain.

The discriminatory power of Rep-PCR is thought to be a little lower than for PFGE, although results seem to correlate well between the methods; some studies suggest that Rep-PCR has superior discriminatory power. The technique is easy to use and can be scaled up for several isolates, although RAPD assays are somewhat easier to perform. As always, a given laboratory should evaluate the methods to determine the best DNA fingerprinting procedure for the number of expected isolates and for the type of equipment and expertise available.

The DiversiLab System (bioMérieux) is an automated Rep-PCR instrument that uses proprietary Rep-PCR primers for different organisms. The system uses a microfluidic chip that evaluates Rep-PCR products. As many as 13 different isolates can be evaluated on one chip. Rep-PCR product fragments are analyzed with the Internet-based *DiversiLab* software to determine strain relatedness. Strain patterns can also be compared with the patterns obtained by other laboratories that use the *DiversiLab* system.

Multilocus variable-number of tandem repeat analysis

Like Rep-PCR, **multilocus variable-number of tandem repeat analysis** (MLVA) takes advantage of repetitive DNA sequences in genomes. MLVA amplifies regions of DNA that contain repeats. Repeated sequences in genomes tend to be unstable, so a given bacterial strain may have more repeats at one locus than a different bacterial strain of the same species. When there are different numbers of repeated sequences at a given locus, this is referred to as a *variable number of tandem repeats* (VNTRs). MLVA maps VNTRs among bacterial strains

by using PCR. This is a useful typing method because it produces quantitative data, it is easy to perform and results are easy to interpret, and it is reproducible.

Multilocus sequence typing

MLST is a derivation of MLEE, described in 1998 by Maiden and coworkers, that analyzes the sequences of genes. MLST is used to identify alleles by determining the internal sequences of **housekeeping genes**. Housekeeping genes code for proteins necessary for basic cellular functions and are constitutive genes (i.e., they are almost always expressed). Both eukaryotic and prokaryotic organisms have housekeeping genes. Bacterial housekeeping genes include the genes for 16S rRNA and dihydrofolate reductase. Because housekeeping genes are almost always expressed, they also make excellent controls for many molecular methods.

For a typical MLST assay, several loci are chosen that represent different internal regions of housekeeping genes. The PCR assay is used to amplify the DNA at each locus; primers are designed to act as a complement to highly conserved regions of the housekeeping genes. Once an amplicon is obtained, it is sequenced with an automated sequencer and given a unique number based on the sequence. Strains of a particular species can then be compared using the same loci. High resolution between strains is possible by comparing these DNA sequences or the numbers representing these sequences.

This method has achieved excellent interlaboratory comparisons; other laboratories merely need to use published primers for loci of the same species to compare data and determine the spread of strains. The method has achieved global recognition, and there are Internet-based databases of strains (<https://pubmlst.org/multilocus-sequence-typing>). The website provides protocols, information, and software for sequence analysis. A drawback of MLST is that it requires an automated sequencer, and the method is expensive compared with PFGE. However, of all methods described in this chapter for DNA fingerprinting of strains, MLST probably has the highest resolution and the greatest chance of interlaboratory agreement.

Molecular diagnostics testing in the clinical microbiology laboratory

Currently, numerous FDA-approved molecular assays are available for several organisms and antimicrobial-resistance genes. Several multiplex molecular assays can identify a large range of organisms by clinical syndrome or specimen site. For example, systems can detect several targets from positive blood cultures using multiplex molecular technology. The BioFire Blood Culture Identification 2 Panel (bioMérieux) can detect different bacteria, yeasts, and antimicrobial-resistance gene targets on one panel. The Verigene system (Luminex, Austin, TX) has both gram-positive and gram-negative blood culture tests for several bacterial and antimicrobial-resistance gene targets. The ePlex (GenMark Diagnostics, Carlsbad, CA) Blood Culture Identification Panels offer detection of many targets for gram-positive bacteria, gram-negative bacteria, and yeasts (including antimicrobial-resistance gene targets

for bacteria). The assays from all of these manufacturers can detect these targets in a relatively short amount of time (1 to 2 hours), depending on the system.

In addition to identification of organisms from positive blood cultures, multiplex assays are available for direct detection of organisms from respiratory, CSF, gastrointestinal, and other clinical samples. Indeed, there are many FDA-approved, highly sensitive and highly specific products on the market, and laboratories must evaluate which system and test is appropriate for their services and patient population.

One area that will continue to grow in clinical microbiology laboratories is nucleic acid sequencing. Despite advances in detection of organisms with large-panel multiplex assays, there are still difficult-to-identify organisms that may need to be identified by other means, such as DNA or RNA sequencing. As organism genome sequencing has increased, large-scale screening of nucleic acids and proteins became available. The information obtained from sequencing an organism's genome allows comprehension of cellular processes, protein associations, and interrelatedness of biological activities. Genomics research, coupled with the use of **nanobiotechnology**, has stimulated the invention of methods such as DNA microarray analysis and proteomics. Techniques such as **DNA microarrays** (and nanoarrays), **proteomics**, and **metagenomics** have the capability to revolutionize the analysis of microorganism populations and disease interpretation and treatment. Not all of these methods are ready for routine use in clinical microbiology laboratories; currently, many are primarily used as research tools.

Sequencing

DNA Sequencing is determining the order of nucleotides in a fragment of DNA; the chain termination method devised by Frederick Sanger is most frequently used. DNA sequencing has been available for years. Initially, the sequencing technique was somewhat labor-intensive, but it is now automated and has been applied to large-scale processes such as whole-genome sequencing. The human genome has been sequenced, as have the genomes of many other eukaryotic and prokaryotic organisms. Whole-genome sequencing is not a technique that clinical laboratories typically perform; however, clinical laboratories have started using small-scale sequencing techniques to identify microorganisms.

Many clinical microbiology laboratories now perform 16S rRNA gene sequencing to confirm the identity of problematic bacterial isolates. Other genes can also be sequenced to determine the identity of an isolate, such as *rpoB* (RNA polymerase B), which is often used to identify mycobacteria. To identify fungi by sequencing, a variety of targets have been used, usually within the rRNA gene complex, encompassing the 18S, 5S.8S, and 28S rRNA genes; the external transcribed spacer regions 1 and 2 that flank the rRNA genes; and the variable internal transcribed spacer regions 1 and 2.

In one popular method, a pair of primers is hybridized to template DNA prepared from bacterial cells, and PCR is performed to amplify a 500- to 1500-bp product. The library of PCR products is then purified with a commercial kit to remove excess primers and template DNA. Two reactions are performed during the next step, called *cycle sequencing*; one reaction uses a forward primer, and the other reaction uses a

reverse primer. In each reaction, the purified PCR amplicons from the previous PCR are used as the DNA template.

In the cycle sequencing reactions, the four standard deoxynucleotide bases (A, C, G, T) are included in the reaction mix, along with low concentrations of chain-terminating nucleotides of each dNTP. These chain-terminating nucleotides are also called *dideoxynucleotides triphosphates* (ddNTPs). Each ddNTP is labeled with a different fluorescent dye. When a labeled ddNTP is incorporated into the growing complementary strand of DNA, it terminates that strand; more dNTPs cannot be added beyond this point. A series of related DNA fragments are therefore synthesized, and these are terminated at the position at which the labeled ddNTP was incorporated. Fragments of every size are generated during this process. The generated fragments are purified to remove unincorporated chain terminators and are then separated by capillary electrophoresis in an automated analyzer. The sequence is thus generated based on fragment size, and a fluorimeter determines the dye on the end of each fragment. Each ddNTP has a different color fluorophore, enabling identification of the ddNTP on the end of each fragment.

Once the sequence has been determined, software is used to compare the generated sequence with a database of known sequences. A most likely identity can then be determined. When examining the relatedness of different species and strains of bacteria by sequencing, **dendrograms** are often used. Different methods of generating dendrograms include the neighbor-joining method, unweighted pair group method with arithmetic averages, and weighted pair group method with arithmetic averages. Generally, these different methods produce comparable results.

To determine the most likely identity of the unknown sequence, the investigator chooses similar organisms for comparison. For example, if the unknown isolate that was sequenced is an oxidase-positive, nonfermenting, gram-negative bacillus, several *Pseudomonas* spp. and related organisms may be chosen from the software database to compare them with the unknown isolate. In addition, an outgroup is chosen; this is a sequence against which all of the other similar sequences are compared. The outgroup should be somewhat related to the other organisms chosen, but still outside the group being studied.

Once the dendrogram has been generated, a horizontal line with a percentage is produced by the software at the top of the dendrogram next to the name of the method used to generate it. This horizontal line can be used as a rough measure of the degree of relatedness or difference between isolates in the dendrogram. To determine relatedness, the two horizontal lines of the two isolates in question are added and then compared with the top horizontal line percentage. Although this method is not completely accurate, it does provide a useful estimate of relatedness. See [Fig. 11.16](#) for a depiction of a dendrogram of different Enterobacterales species, generated with the *MicroSeq* software package (Life Technologies, Grand Island, NY). *P. aeruginosa* was chosen as the outgroup for this dendrogram.

Pyrosequencing

Pyrosequencing is a sequencing by synthesis technique that does not require labeled nucleotides or primers and does not require a postreaction electrophoresis step. It is a rapid

Fig. 11.16 Example of a dendrogram showing the genetic relationships among different Enterobacteriales species based on 16S ribosomal RNA gene sequencing.

sequencing technique that generates approximately 20– to 50–base-long sequences per primer, so this technique is best used for short sequences. Sanger sequencing is the best choice for longer DNA fragments.

Pyrosequencing uses the enzymes DNA polymerase, adenosine triphosphate (ATP) sulfurylase, luciferase, and apyrase and the substrates adenosine 5'-phosphosulfate (APS) and luciferin. A sequencing primer is hybridized to a single-stranded DNA template and incubated with the enzyme-substrate mix. The four different nucleotides are then added one at a time in a defined order. If the added nucleotide base-pairs with the DNA template, the DNA polymerase will incorporate the nucleotide with the release of pyrophosphate (PPi). In the presence of the substrate APS, ATP sulfurylase converts PPi to ATP. Luciferase then uses the newly formed ATP to convert luciferin to oxyluciferin, which releases light. The light is detected with a charge-coupled device camera. This is a quantitative and real-time process. Each light signal indicates that a nucleotide has been incorporated by DNA polymerase. The generated light is visualized as a peak, and the height of the peak indicates how many nucleotides were incorporated. The enzyme apyrase degrades excess nucleotides. After degradation, a new nucleotide is added, and the process begins again. The nucleotide sequence of interest is thus determined from the light peaks that occur during the nucleotide addition and incorporation process.

Pyrosequencing was used initially to determine sequences in mutation analyses of human DNA. However, the technique has also been used to identify microorganisms and to detect various antimicrobial-resistance genes in *M. tuberculosis*.

Next-generation sequencing

Next-generation sequencing (NGS) brings high throughput and accuracy to sequencing via automated platforms.

Several different platforms are available, such as the HiSeq and MiSeq systems from Illumina (San Diego, CA) and Ion Torrent (Thermo Fisher Scientific). Each of these technologies differs in the length of sequence that is read by the platform. In addition, the sequencing method, run time, and cost are different. Throughput (speed) is enhanced by NGS methods because numerous sequencing reactions can be run by the platforms in parallel, and the chemical reaction can be combined with signal detection.

DNA microarrays and nanoarrays

The term *DNA microarray* refers to a grouping at the micron level of DNA molecules attached to a solid support, such as silicon chips, glass, or plastic. A DNA microarray is sometimes referred to as a *DNA chip*, or *gene chip*. A DNA microarray gives investigators the potential to evaluate gene expression from an entire organism, or even from several organisms. DNA microarrays are often used to analyze transcriptional levels of genes during a particular disease. This technique has been used for many purposes, such as determining mutations, identifying new genes, monitoring response after treatment, determining binding sites for transcription factors, and identifying pathogens. For example, a DNA microarray could be used to simultaneously detect several pathogens. This could be applied to pathogens of interest in clinical and veterinary medicine, for public health issues, and for homeland security (e.g., screening for potential biothreat agents on one DNA chip).

A DNA microarray is constructed with special micro instruments that are capable of placing microscopic spots of DNA on a solid surface. Thousands or more can be placed on one chip. These spots of DNA are commonly termed *reporters*. DNA fragments from a specimen of interest are labeled with a fluorescent dye and incubated with the DNA on the chip. Unbound strands are removed by washing. A scanner reads fluorescence that develops only when a hybrid occurs. The hybrid that fluoresces is matched to the known map of the DNA chip. For example, an investigator may have a DNA microarray constructed with a single-stranded DNA sequence from many pathogenic respiratory bacteria.

Alternatively, RNA can be extracted from a patient sample, and reverse transcriptase is used to prepare large amounts of cDNA from each transcript. A fluorescent probe is enzymatically attached to the cDNA produced. The tagged cDNA is then incubated with the DNA on the chip and analyzed by a screener. A fluorescent signal from one DNA spot would indicate a hybrid and could imply a disease role for a particular organism. Amplification procedures can also be coupled to DNA microarrays for a potentially more powerful identification and analytic tool.

With the recent increase in the use of nanotechnology, nanoarrays (nanochips) have been developed. A nanoarray has molecules placed on a surface at defined locations, with nanometer spatial resolution. Like microarrays, nanoarrays are being developed for genomics and proteomics applications, such as organism identification. Nanotechnology applied to a chip does not need coupled reporters, as DNA microarrays do, and can screen more molecules; therefore nanoarrays are more sensitive and have higher throughput compared with DNA arrays.

Proteomics

Genomic sequencing has also led to an increased understanding of protein interactions and expression in cells. Proteomics is the study of proteins on a cellular level. Like genomics, proteomics is a large-scale process, but it is probably more complicated than analysis at the gene and transcriptional levels. Protein expression changes, for example, from cell to cell, among different disease states, during the life cycle of a cell, and during responses to changing environmental conditions. In addition, proteins with the same genetic origin can be vastly different as a result of alternative splicing of their coding RNAs or after posttranslational modifications.

The genome of an organism is the sum of the genetic material; the proteome of an organism is the sum of proteins found during all changing conditions for a cell. Thus the proteome is often larger and more complex than the genome. Proteomics is used to determine protein expression in disease conditions, such as cancers, genetic diseases, and other diseases, including microbial infections. For example, proteins identified in a certain disease state may become targets for new laboratory tests. In another example, therapy for a given condition may be based on the protein expression involved in the disease state.

Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry

Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry is a technology that is used for rapidly identifying microorganisms, including fungi. This technique has been used for years in chemistry to analyze molecular molar masses. Microbial identification can be made in minutes from isolated colonies. Apart from a one-time, up-front instrument cost, MALDI-TOF analysis is very cost-efficient. Currently, two MALDI-TOF platforms are FDA approved for use in the United States: the VITEK MS (bioMérieux) and the MALDI Biotyper (Bruker, Billerica, MA; Fig. 11.17).

After an organism is recovered on solid media, a small amount of the colony is applied to a spot on a metal target (Fig. 11.18). An energy-absorbing chemical matrix solution is added to the colony material. The matrix solution consists of a crystallized chemical such as α -cyano-4-hydroxycinnamic acid, water, and an organic solvent such as acetonitrile. The organic solvent (and water) extracts proteins from the microorganisms on the target. The matrix solution is allowed to dry onto the colony material; the solvent will vaporize, and this results in the colony proteins being co-crystallized with the matrix chemical.

The metal target is then loaded into the ionization chamber of the MALDI-TOF mass spectrometer, and the co-crystallized organism protein/matrix lattice is pulsed with an ultraviolet laser. The activity of the laser causes the matrix to transfer protons to the colony material, producing singly protonated ions of the proteins, which gives these proteins a positive charge. The matrix also absorbs the laser light, converts it to heat energy, and is vaporized (desorption), along with the proteins, in nanoseconds. The ionized proteins then enter a flight tube. An electrode then accelerates the positively charged ions into a mass analyzer. The mass analyzer separates the ions by their mass-to-charge ratio. The amount of

Fig. 11.18 Metal target, Bruker MALDI Biotyper system (Bruker). (Image courtesy Steve D. Mahlen.)

time it takes for the ions to move through the analyzer and be detected is the time of flight. Each protein generates a distinct signal, and every microorganism has a unique set of protein signals. A mass spectrum is thus generated for each microorganism and is unique for each species. Company-specific software is used to identify the organism based on a comparison with a reference database of spectra.

Metagenomics

It is estimated that only about 1% of all prokaryotes from most environments on our planet are culturable in the laboratory. Understanding the complexity and interactions of mixed microbial populations may yield valuable information that can affect human health and our association with the environment. For example, research has shown that the trillions of bacterial cells that make up the human gut microbiota influence human physiology, metabolism, nutrition, and immune function. The gut contains an estimated 1000 bacterial species and 100-fold more genes than are found in the human genome. Each person has a unique gut microbiota as personal as a fingerprint. It is believed that about 90% of all human diseases can be linked to the microbiome in one way or the other. Still, most of our microbiome is nonculturable.

Metagenomics was developed to identify nonculturable microorganisms; it is the identification of microbial genomes from mixed populations using molecular techniques. Both sequencing and gene expression methods have been used in metagenomics. This method has great application in environmental studies; for example, metagenomics has been applied to study microbial populations from soil, oceans, and biofilms. Metagenomics has also been used to study populations of microorganisms from the human body, such as bowel or urogenital tract microbiota. Many human infections are polymicrobial and involve biofilms (see [Chapter 31](#)). It is possible that many of the bacteria that play a role in infectious processes are not cultivable in the laboratory. Scientists from the J. Craig Venter Institute (JCVI) are traveling the globe by yacht to sample marine microorganisms under a project termed the *Sorcerer II Expedition*. In short, the potential application of metagenomics is limited only by the imagination.

Sherlock microbial identification system

The Sherlock Microbial Identification System (MIDI, Newark, DE) is based on the 9- to 20-carbon fatty acid composition of microorganisms ([Fig. 11.19](#)). The Sherlock system examines which fatty acids are present as well as their relative concentration (percentage). Fatty acids are located in the plasma membrane of bacteria and, depending on environmental conditions, are modified by the bacteria. For this reason, it is important that growth conditions are well standardized for accurate identification.

The standard incubation conditions for most aerobic bacteria are tryptic soy agar incubated at 28°C for 24 hours. After incubation, a loopful of bacteria is suspended in a methanolic base and heated for 30 minutes in a boiling water bath. During this step, cells are lysed, and the fatty acids are cleaved from the lipids and converted to the sodium salt. After cooling, the sample is mixed with a solution of methanol and hydrochloric acid to methylate the fatty acids to fatty acid methyl esters. The fatty acid methyl esters are extracted, washed, and injected into a high-resolution gas chromatograph. The fatty acid esters are separated by the column in the gas chromatograph, and a chromatogram is created. The size of the molecule and degree of saturation determine the retention time in the column. The fatty acids are identified by their retention time compared with standards, and the height of the peak determines the concentration. Typical identification requires 1.5 to 2 hours. The Sherlock system compares the fatty acid

Fig. 11.19 Sherlock Microbial Identification System incorporates Agilent gas chromatograph (#6850). (Courtesy Agilent Technologies, Inc., Palo Alto, CA.)

profile of the unknown with the database of approximately 1500 organisms. MIDI also markets a high-performance liquid chromatography system for the identification of *Mycobacterium* spp. In a study of the identification of environmental airborne bacteria that included *Bacillus* spp., *Staphylococcus* spp., *Micrococcus* spp., and *Acinetobacter*, MIDI correctly classified 75% (77/103) of isolates.

Nanomedicine

Nanotechnology is the creation of functional materials, devices, and systems through the understanding and control of matter at dimensions in the nanometer scale, in which new functionalities and properties of matter are observed and harnessed for a broad range of applications. *Nanomedicine* is defined as the application of nanotechnology in medicine, including diagnosing and treating diseases and repairing damaged tissues such as bone, muscle, and nervous tissue. The advantages of incorporating drugs into nanoparticles are to minimize the side effects of the drug on the body while maximizing the efficacy of the drug. Nanomedicine has the potential to eliminate the risk of side effects by preventing the spread of drugs to undesired locations of the body and may also help develop cost-effective treatments for many chronic diseases. Nanoparticles can be used to deliver antimicrobial agents to the site of infection; see [Chapter 12](#).

Nanotechnology can also provide sensitive and specific diagnosis of infectious diseases by selectively capturing and distinguishing microbial target molecules from other substances in a biological sample. Nanoparticles coupled to probes (e.g., antibodies and nucleic acids), with affinity for microbial biomarkers, can selectively recognize microbes. Nanomaterials used for microbial diagnosis include magnetic, gold, and fluorescent nanoparticles.

Magnetic nanoparticles, such as superparamagnetic iron oxide nanoparticles (SPIONs), have been used as markers to detect nucleic acid sequences of five species of yeasts in the

genus *Candida* in human blood. Hybridization of oligonucleotides labeled with SPIONs to amplified *Candida* DNA produces large changes in the sample's T2 magnetic resonance signal. The assay takes about 3 hours to perform. Gold nanoparticles have also been used as oligonucleotide labels for detecting bacterial DNA sequences, such as the *mecA* gene coding for methicillin resistance in *S. aureus*. Antibody-conjugated silica nanoparticles that encapsulate thousands of fluorescent dye molecules produce an amplified signal that can detect a single bacterial cell in tissue in less than 20 minutes.

POINTS TO REMEMBER

- The three basic nucleic acid molecular diagnostics applications used in clinical microbiology laboratories are (1) nucleic acid hybridization assays, (2) nucleic acid amplification techniques, and (3) strain typing techniques.
- Nucleic acid hybridization assays detect nucleic acid targets with labeled probes. These assays can occur on a solid support, in situ, or in a solution.
- Amplification procedures exponentially increase the amount of target nucleic acid, probe, or signal in the presence of target nucleic acid. Amplification procedures include PCR and variants of PCR (e.g., RT-PCR, multiplex PCR, and nested PCR), NASBA, TMA, bDNA assay, and hybrid capture.
- PCR is frequently used in laboratories and consists of three basic steps: denaturation of target DNA, primer annealing, and primer extension. These steps are repeated multiple times (a cycle) to exponentially increase the amount of target DNA to levels high enough for easy detection.
- Real-time PCR is a popular detection technique used to view PCR products as they are formed in the reaction. The technique is also used to quantitate DNA.
- RT-PCR detects target RNA. The initial step of RT-PCR produces cDNA copies of RNA with reverse transcriptase. The cDNA is then amplified by PCR. RT-PCR, like standard PCR, is often analyzed by real-time PCR.
- Multiplex PCR uses more than one primer set during PCR. One of the primer sets often targets an internal control gene, while the other primer set is used to amplify the target gene.
- Nested PCR is essentially two different PCR assays that are run one after the other. The first assay uses a primer pair that amplifies target DNA. The PCR product is then used as the DNA template for the second PCR assay. The second assay primers are internal to the first PCR product.
- NASBA and TMA are performed at a single temperature (isothermal) and produce large amounts of RNA copies of the target nucleic acid. NASBA uses three enzymes: reverse transcriptase, RNase H, and T7 polymerase. In TMA, a reverse transcriptase with RNase H activity is used along with a T7 RNA polymerase.
- Branched DNA assays use several different probes to amplify the signal instead of the nucleic acid sequence. A branched probe that allows many detection probe molecules to bind to it is used to amplify the signal.
- Hybrid capture uses an RNA probe to bind to target DNA and form an RNA:DNA hybrid. A capture probe is added that binds the hybrid to a solid support. Detection probes are then added that amplify the signal.
- Invader technology uses two oligonucleotides (a primary probe oligonucleotide and an Invader oligonucleotide) that anneal to target DNA. When these two probes anneal to the target DNA, they overlap. The resulting structure is targeted by the enzyme cleavase, which releases a 5' flap that then anneals to a FRET oligonucleotide. This creates a new invasive structure that cleavase acts on. This releases a signal. There is a large excess of probe in the mixture, so many signals are generated if the target sequence is present.
- Strain typing methods are used generally for epidemiologic purposes. Either amplification-dependent or amplification-independent methods are used to detect different strain types. Amplification-independent methods include Southern blotting, plasmid profile analysis, restriction enzyme digestion of chromosomal DNA, PFGE, and MLEE. Amplified methods include RAPD, Rep-PCR, and MLST.
- Of the amplification-independent typing procedures, PFGE is probably used the most by clinical microbiology laboratories. Chromosomal DNA from strains of interest is digested with a restriction enzyme and separated by an electrophoresis system that electrically pulses the large fragments of DNA through an agarose gel. Different strains will have unique banding patterns.
- Among amplification-dependent methods, RAPD-PCR uses random primers that anneal to random sequences in the genome of a given strain. After amplification by PCR, different strains will have unique patterns. Rep-PCR uses primers that anneal to repeating palindromic sequences in a genome. The DNA in between the palindromic sequence repeats is amplified by PCR, resulting in unique patterns for individual strains.
- MLVA amplifies variable numbers of repeats in bacterial genomes.
- MLST identifies mutations in genes by sequencing different loci from strains after PCR amplification. The technique produces excellent intralaboratory and interlaboratory comparisons, although the procedure is expensive and requires sequencing equipment.
- Different sequencing platforms have been developed to identify the sequence of whole organisms or certain regions to yield a highly accurate and sensitive diagnosis.
- Metagenomics allow the identification of nonculturable species using genome sequencing.
- Protein profiles of microorganisms can be determined using MALDI-TOF mass spectrometry. The profiles can be compared with a database for identification of unknown microorganisms.
- Fatty acid profiles of bacteria grown under standard conditions can be detected using gas liquid chromatography and high-performance liquid chromatography. The profiles can be compared with a database to identify the unknown microorganism.
- Nanoparticles, such as magnetic nanoparticles, gold, and fluorochromes, have been used to label probes in the detection of microbial pathogens.

LEARNING ASSESSMENT QUESTIONS

1. Which of the following statements is true regarding Southern blotting?
 - a. It detects transcripts after restriction enzyme digestion and separation by agarose gel electrophoresis.
 - b. It detects a DNA target after restriction enzyme digestion and separation by agarose gel electrophoresis.

- c. It detects protein polymorphisms after separation by electrophoresis.
 - d. It is an amplification technique that analyzes a particular DNA target.
2. Which of the following probe labels is most often used for nucleic acid hybridization reactions in clinical microbiology laboratories?
 - a. Chemiluminescent
 - b. ^{32}P
 - c. ^{35}S
 - d. ^3H
 3. Which of the following is not a component of a standard polymerase chain reaction (PCR) assay?
 - a. Deoxynucleotides
 - b. Primers
 - c. Restriction enzymes
 - d. Magnesium
 4. Which of the following is an advantage of using nucleic acid amplification procedures in clinical microbiology laboratories?
 - a. They are highly sensitive.
 - b. Results are obtained more rapidly compared with standard microbiology techniques such as culture.
 - c. They have increased sensitivity compared with standard microbiology procedures.
 - d. All the above.
 5. Which of the following describes branched DNA detection?
 - a. A form of PCR that analyzes transcripts
 - b. A signal amplification method that uses capture, target, preamplifier, amplifier, and labeled probes
 - c. A signal amplification method that uses RNA probes, capture probes, and alkaline phosphatase-labeled probes
 - d. A target amplification method that uses reverse transcriptase, ribonuclease H (RNase H), and T7 RNA polymerase
 6. Which of the following procedures does not use fluorescence resonance energy transfer (FRET)?
 - a. 5' nuclease assay
 - b. Scorpion primers
 - c. Molecular beacons
 - d. Transcription-mediated amplification
 7. Reverse transcription PCR uses which of the following?
 - a. Reverse transcriptase to produce complementary DNA (cDNA) from transcript
 - b. T7 RNA polymerase to produce transcript from cDNA
 - c. T7 RNA polymerase to produce cDNA from transcript
 - d. RNase H to degrade RNA in DNA:RNA hybrids
 8. Which of the following factors does not influence hybridization reactions?
 - a. pH
 - b. Temperature
 - c. Length of the target's genome
 - d. Degree of complementarity between the probe and target nucleic acid
 9. Which of the following strain typing procedures has probably the greatest interlaboratory agreement?
 - a. Multilocus enzyme electrophoresis
 - b. Multilocus sequence typing
 - c. Pulsed-field gel electrophoresis
 - d. Random amplified polymorphic DNA analysis
 10. Which of the following is not true about the 5' nuclease assay?
 - a. It is also referred to as the *TaqMan assay*.
 - b. It uses a probe with a 5' fluorophore and a 3' quencher that is degraded by the action of DNA polymerase.
 - c. It uses FRET to keep background fluorescence low.
 - d. It uses a hairpin-shaped probe with a fluorophore on the 5' end and a quencher on the 3' end.
 11. For most bacteria, which target is usually sequenced to confirm the identity of problematic isolates?
 - a. *rpoB*
 - b. 16S ribosomal RNA
 - c. Internal transcribed spacer region 1
 - d. External transcribed spacer region 1

Antibacterial mechanisms of action and bacterial resistance mechanisms

Brandon C. Ellis and Donald C. Lehman

CHAPTER OUTLINE

Antimicrobial targets and mechanisms of action, 252

- Inhibition of bacterial cell wall biosynthesis, 252
- Inhibition of folate synthesis, 258
- Interference with DNA replication, 258
- Interference with DNA transcription, 258
- Interference of mRNA translation, 258
- Combined mechanisms of action, 260

Mechanisms of antimicrobial resistance, 260

- Origins of antimicrobial resistance, 260
- Intrinsic mechanisms of resistance, 261
- Acquired mechanisms of resistance, 263

β -Lactamase inhibitors, 266

Dissemination of Resistance Determinants, 267

Nanotechnology to deliver therapeutic agents, 268

Bibliography, 270

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Categorize the different classes of antibacterial agents based on mode of action.
2. Contrast the differences between intrinsic and acquired mechanisms of antimicrobial resistance.
3. Discuss how the spectrum of β -lactam antibiotics can be expanded to treat infections caused by β -lactamase-producing bacteria.
4. Discuss how “antibiotic stewardship” can preserve the effectiveness of antimicrobial agents.
5. Describe the mechanisms used by bacteria to exhibit antimicrobial resistance, (e.g., efflux pumps, enzymatic inactivation).
6. Compare intrinsic and acquired antimicrobial drug resistance in bacteria.
7. Correlate the presence of extended-spectrum β -lactamases in gram-negative bacteria with drug resistance.
8. Discuss the mechanisms used by microorganisms to disseminate resistant determinants.
9. Explain how nanomedicine delivery systems can more effectively treat bacterial infections compared with free drugs.
10. Discuss potential alternatives to treat antimicrobial-resistant infections.

KEY TERMS

Acquired resistance

Aminoglycosides

Antibiotic

Antibiotic stewardship

Antimicrobial agent

Avibactam

β -Lactam antibiotics

β -Lactam ring

β -Lactamase inhibitors (BLIs)

β -Lactamases

Biofilms

Clavulanic acid

Conjugation

DNA replication

DNA transcription

Efflux pumps

Glycopeptides

Glycylcyclines

Induced resistance

Insertion sequences (ISs)

Integrons

Intrinsic resistance

Ketolides

Linezolid

Macrolides

mRNA translation

Oxazolidinones

Penicillin-binding proteins (PBPs)

Peptidoglycan

Persister cells

Plasmids

Polymyxin

Porins

Quinolones

Relebactam

Streptogramin

Sulbactam

Sulfamethoxazole (SMZ)

Tazobactam

Tetracycline

Tigecycline

Tolerance

Transcription

Transduction

Transformation

Transposons (Tns)

Trimethoprim (TMP)

Case in point

A 12-year-old male patient had acute abdominal pain with fever. The patient had been well, except for a sinus infection treated with amoxicillin-clavulanate. He finished a 10-day course of treatment 4 days before the onset of abdominal pain. He began a prophylactic regimen of ampicillin-sulbactam and underwent an appendectomy. Treatment with ampicillin-sulbactam was discontinued 2 days after surgery, and treatment with amoxicillin-clavulanate was begun. The following day, the patient exhibited diarrhea, and a stool culture yielded *Salmonella enterica* serotype Typhimurium. The isolate

was reported to be resistant to a wide range of antimicrobial agents, including ampicillin, chloramphenicol, tetracycline, sulfisoxazole, kanamycin, streptomycin, cephalothin (first-generation cephalosporin), and extended-spectrum cephalosporins (e.g., ceftriaxone, ceftazidime, and cefoxitin). An epidemiologic investigation found that the patient's father had treated calves with severe diarrhea from his herd and three other herds 1 month before the patient became ill. Stool specimens from ill cattle in each herd were analyzed and yielded *S. enterica* serotype Typhimurium. Antimicrobial susceptibility testing revealed that the isolate from the patient and one of the isolates from cattle had an identical resistance pattern (antibiogram). Molecular typing by pulsed-field gel electrophoresis showed that the *S. enterica* serotype Typhimurium isolated from the patient and cattle had indistinguishable deoxyribonucleic acid patterns. Further studies were conducted to characterize the mechanisms of resistance and their possible means of transmission.

Issues to consider

After reading the patient's case history, consider:

- The role empiric therapy plays in the treatment of disease
- Whether prior antimicrobial treatment provides insight into possible mechanisms of resistance
- How the bacterial targets of the different drug classes differ
- Which antimicrobial resistance mechanisms can produce the same resistance phenotype
- Which mechanism of resistance is most likely to produce cross-resistance to multiple classes of agents
- The role β -lactamase inhibitors may have played in the treatment of the infection

The discovery of potent, relatively nontoxic antimicrobial therapeutic agents was perhaps the foremost medical advance of the 20th century. **Antimicrobial agents** include antibacterials, antifungals, antiseptics, disinfectants, sterilants, and preservatives; all have the capacity to kill or suppress the growth of microorganisms. Antimicrobial agents are an essential component of the practice of medicine. They treat, prevent, and control the dissemination of microbial pathogens in and on animal tissue and nonliving materials (fomites). The term **antibiotic** has been traditionally reserved for compounds that are naturally produced by living microorganisms, such as bacteria and fungi. The term has come to be more widely applied to any natural, semi-synthetic, or synthetic molecule used to treat or prevent disease. Antimicrobial agents can be natural products, semi-synthetic variants of natural products, or synthetic chemicals designed to block key biochemical pathways or interfere with cellular structures, leading to growth inhibition or bacterial death. Although numerous antimicrobial classes have been discovered, with different modes of action, bacteria evolve and adopt numerous strategies to counteract the action of these agents.

Antimicrobial drug resistance was observed soon after the discovery of antibiotics. It is a natural consequence of drug exposure and results from the use and inappropriate use of antimicrobial agents. The World Health Organization (WHO) estimates that by 2050 there will be at least 10 million deaths per year resulting from infections with drug-resistant bacteria. Besides deaths, it is estimated that drug-resistant

infections could reduce world gross domestic production by 2% to 3% per year, imposing a global economic burden amounting to trillions of dollars. Because of these projections, the WHO has listed antimicrobial resistance as a global public health threat. Antimicrobial use induces selection pressure, allowing only the fittest and most resistant bacterial populations to thrive and thereby displace susceptible populations. Over time and with the use of multiple antimicrobial agents, resistant strains predominate and often acquire multidrug resistance (MDR; also multidrug-resistant). Not only do bacteria acquire the mechanisms necessary to withstand the toxic effects of antimicrobial agents, but they also acquire elaborate mechanisms to mobilize and disseminate genes involved in these successful strategies via plasmids, **transposons (Tns)**, integrons, and other mechanisms (see Chapter 1).

The adaptive strategies used by microorganisms to survive the hostile antimicrobial environment are remarkable in their evolution and complexity. Deoxyribonucleic acid (DNA) sequence data show that many different resistance determinants can amass in linked clusters on plasmids or the chromosome, so antimicrobials of a different class, including substances such as disinfectants or heavy metals, can select for MDR bacteria. Although resistance, particularly MDR, appears to be most serious in certain bacterial species, this situation may be shifting as large, mobile MDR elements spread to new bacterial hosts in different environments.

This chapter introduces the mechanisms of action of antibacterials and how bacteria become resistant to these agents. For information on the action of antifungals and antivirals, see Chapters 27 and 29, respectively. Intrinsic and acquired mechanisms that facilitate resistance to important therapeutic regimens are included. Many of these resistance mechanisms may be generalized to other pathogens. Furthermore, multiple mechanisms of resistance may be present simultaneously in a single microorganism, resulting in the MDR phenotypes frequently observed in clinical settings.

Case check 12.1

The patient in the Case in Point suffered from an infection by an MDR bacterium. The continuous development of new antimicrobial classes of compounds historically has helped medical science stay ahead of developing resistance. However, the number of new antimicrobial agents being brought to the market has undergone a steady decline in the past two decades, making drug resistance and its associated clinical failure an issue of global public health concern. The WHO has published a list of priority pathogens for which new antimicrobials are critically needed. This list contains carbapenem-resistant *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and Enterobacterales.

Only a few new classes of antimicrobial drugs have been approved by the U.S. Food and Drug Administration (FDA) in the past few years: oxazolidinone (2000), lipopeptide (2003), pleuromutilin (2007), and macrolactone (2011). Efforts to develop new analogues of older classes by adding chemical moieties that provide some protection against one or more of the known resistance mechanisms are ongoing. These efforts have resulted in the development of several

well-known classes such as semi-synthetic and synthetic β -lactams, oxazolidinone, ketolides, glycyclines, and glycopeptides. Further exploration of antimicrobial targets, new and old, is vital to the discovery of new antibacterial drugs to address the escalating MDR problem and overcome the loss of effectiveness over time for existing drugs.

To address the issue of MDR infections, programs emphasizing *antibiotic stewardship* have been initiated by health professionals. **Antibiotic stewardship** refers to the appropriate use of antimicrobials to maximize their current effects and improve their chances of being available for future generations. To encourage the development of antimicrobial drugs, new models for promoting their development have been proposed. These models were a focus of the first G20 Health Ministers' Meeting held in May 2017 in Berlin, Germany. Innovative public-private partnerships, such as Combating Antibiotic Resistant Bacteria Biopharmaceutical Accelerator (CARB-X), were formed to assist in the development of new therapeutics, vaccines, diagnostics, and devices to address the issue of MDR infections.

The development of rapid diagnostic tests for use at the patient's bedside (i.e., point of care) to detect the presence of bacterial pathogens and determine their susceptibility to antimicrobials is also essential to reducing the incidence of drug-resistant infections. Diagnostics based on DNA assays such as the polymerase chain reaction and other nucleic acid amplification tests might provide the means to meet the challenge of reducing MDR infections by quickly identifying resistant strains.

In addition, alternatives to the use of antimicrobial drugs are being proposed. Alternatives to antimicrobials are defined as noncompound approaches, products other than classic antibacterial agents, which target bacteria or any approach that targets the host. Currently, the most advanced approaches are antibodies, probiotics, and vaccines. In addition to these therapeutics, the use of bacteriophage therapy as a complement or alternative to traditional antimicrobials is being explored; however, this area is still in the research and development stage.

Antimicrobial targets and mechanisms of action

The most widely used antimicrobial agents interfere with cellular processes and can be grouped into one of six target categories (Table 12.1):

- Bacterial cell wall biosynthesis
- Bacterial cell membranes
- Bacterial protein biosynthesis
- DNA replication and repair
- RNA synthesis
- Folate biosynthesis

Approximately 23 unique classes and 18 subclasses of clinically useful antibacterials representing approximately 100 agents are used in clinical medicine. The classification scheme is complex, and the number of antimicrobials continue to expand as new classes emerge or existing classes are

modified. Antimicrobial agents target anabolic cellular processes such as cell wall synthesis, folate synthesis, DNA replication, ribonucleic acid (RNA) transcription, and messenger RNA (mRNA) translation. These targets are critical to the survival of microorganisms and are sufficiently distinct from eukaryotic cells to permit selective toxicity. Understanding the mechanisms of action of antimicrobial agents provides insight into strategies used by microorganisms to evade their toxic effects. Fig. 12.1 shows the primary cellular process of antibacterial action for major classes of antimicrobial agents (see Table 12.1).

Inhibition of bacterial cell wall biosynthesis

Many antibacterial agents function by targeting bacterial cell wall synthesis. Cell walls are not found in mammalian cells and differ in composition among various bacterial species. Therefore cell wall synthesis provides a number of potential targets for antimicrobial drugs.

Gram-positive and gram-negative bacteria have a multi-layered cell wall structure composed of an inner cytoplasmic membrane, a peptidoglycan layer, and in gram-negative bacteria, a second outer membrane (Fig. 12.2). The cytoplasmic membrane, composed of phospholipids and proteins, surrounds the cytoplasm, acts as an osmotic barrier, and is the location of the electron transport system responsible for energy production.

Peptidoglycan (murein) is a unique mucopolysaccharide constituent of the bacterial cell wall. The quantity of this polymer and its location within the cell envelope are different between gram-negative and gram-positive bacteria. The peptidoglycan layer is made up of chains of alternating disaccharide subunits of *N*-acetyl-D-glucosamine and *N*-acetyl-D-muramic acid (NAM; Fig. 12.3). The NAM subunit has a short peptide chain attached that mediates cross-linking of parallel glycan molecules in mature peptidoglycan. This peptide consists of L- and D-amino acids, which typically end in D-alanyl-D-alanine (D-Ala-D-Ala). Cross-links between neighboring peptide side chains impart mechanical strength to the molecule and present opportunities for biochemical diversity in the types of cross-links within and among different bacterial species. In gram-positive bacteria, the peptidoglycan layer is substantially thicker and more multilayered than in gram-negative bacteria. The outer membrane of gram-negative bacteria is composed of lipopolysaccharides (LPSs), phospholipids, and porin proteins and is separated from the cytoplasmic membrane by the periplasmic space and a thin layer of peptidoglycan.

Peptidoglycan biosynthesis has four major stages: (1) synthesis of precursors in the cytoplasm; (2) transport of lipid-bound precursors across the cytoplasmic membrane; (3) insertion of glycan units into the cell wall; and (4) transpeptidation linking and maturation. D-Cycloserine and bacitracin inhibit the first two steps, respectively. The most used inhibitors of cell wall biosynthesis, β -lactams and glycopeptides, act on processes in stages 3 and 4. Under normal growing conditions, peptidoglycan synthesis proceeds by the ligase-mediated formation of D-Ala-D-Ala, a precursor used to form UDP-NAM-acetyl-muramyl-pentapeptide (see

Table 12.1 Antimicrobial agent targets and pathways

Drug type	Drug name(s)	Derivation	Species range	Primary target	Pathways affected
Fluoroquinolones^a					
DNA synthesis inhibitor	Nalidixic acid, ciprofloxacin, levofloxacin, gemifloxacin, moxifloxacin, norfloxacin	Synthetic	Aerobic gram-positive and gram-negative species, some anaerobic gram-positive species (<i>Clostridium perfringens</i>), and <i>M. tuberculosis</i>	Topoisomerase II (DNA gyrase), topoisomerase IV	DNA replication, SOS response, cell division, ATP generation, TCA cycle, Fe-S cluster synthesis, ROS formation, and envelope and redox-responsive two-component systems
Sulfonamides and trimethoprim					
DNA synthesis inhibitor	TMP/SMX (brand names Bactrim, Septra)	Synthetic	Aerobic gram-positive and gram-negative species	Tetrahydrofolic acid synthesis inhibitors	Nucleotide biosynthesis and DNA replication
Rifamycins					
RNA synthesis inhibitor	Rifampin, rifapentine, rifaximin, rifabutin	Natural and semi-synthetic forms of ansamycins (derived from <i>S. mediterranei</i>)	Gram-positive and gram-negative species, and <i>M. tuberculosis</i>	DNA-dependent RNA polymerase	RNA transcription, DNA replication and SOS response
β-Lactams^a					
Cell wall synthesis inhibitor	Penicillins (penicillin G, penicillin V, amoxicillin, ampicillin, oxacillin, ticarcillin, piperacillin), cephalosporins (cefadroxil, cephalexin, cefprozil, cefazolin, cefdinir, cefiderocol, cefoxitin, cefotaxime, cefotetan, ceftaroline, ceftriaxone, cefuroxime, ceftazidime, cefepime), carbapenems (doripenem, ertapenem, imipenem, meropenem), monobactam (aztreonam)	Natural and semi-synthetic forms of carbonyl-lactam ring-containing azetidinone molecules (from <i>P. notatum</i> , <i>C. acremonium</i> , and <i>S. cattleya</i>)	Aerobic and anaerobic gram-positive and gram-negative species	Penicillin-binding proteins	Cell wall synthesis, cell division, autolysin activity (regulated by LytSR-VncRS two-component system), SOS response, TCA cycle, Fe-S cluster synthesis, ROS formation, and envelope and redox-responsive two-component systems
Glycopeptides and glycolipopeptides					
Cell wall synthesis inhibitor	Vancomycin, teicoplanin, oritavancin, telavancin, dalbavancin	Natural and semi-synthetic forms of amino sugar-linked peptide chains (for glycopeptides) or of fatty acid-bearing, amino sugar-linked peptide chains (for glycolipopeptides) derived from actinobacteria	Gram-positive species	Peptidoglycan units (terminal D-Ala-D-Ala dipeptide)	Cell wall synthesis, transglycosylation, transpeptidation, and autolysin activation (VncRS two-component system)
Lipopeptides					
Cell wall synthesis inhibitor	Daptomycin	Natural and semi-synthetic forms of fatty acid-linked peptide chains (from <i>S. roseosporus</i>)	Gram-positive species (daptomycin), gram-negative species (polymyxins)	Cell membrane	Cell wall synthesis and envelope two-component systems
Oxazolidinones					
Protein synthesis inhibitor	Linezolid, tedizolid	Natural and synthetic	Gram-positive species and <i>M. tuberculosis</i>	50S ribosome	Protein synthesis by preventing ribosome assembly

Continued

Table 12.1 Antimicrobial agent targets and pathways – Cont'd

Drug type	Drug name(s)	Derivation	Species range	Primary target	Pathways affected
Aminoglycosides					
Protein synthesis inhibitor	Gentamicin, kanamycin, neomycin, streptomycin, tobramycin, amikacin	Natural and semi-synthetic forms of amino sugars (-mycins from <i>Streptomyces</i> spp. and -micins from <i>Micromonospora</i> spp.)	Aerobic gram-positive and gram-negative species, and <i>M. tuberculosis</i>	30 S ribosome	Protein translation (mistranslation by tRNA mismatching), ETC, SOS response, TCA cycle, Fe-S cluster synthesis, ROS formation, and envelope and redox-responsive two-component systems
Tetracyclines and glycyl cyclines					
Protein synthesis inhibitor	Tetracycline, doxycycline, minocycline, tigecycline	Natural and semi-synthetic forms of four-ringed polyketides (from <i>S. aureofaciens</i> and <i>S. rimosus</i>)	Aerobic gram-positive and gram-negative species	30 S ribosome	Protein translation (through inhibition of aminoacyl-tRNA binding to ribosome)
Macrolides					
Protein synthesis inhibitor	Erythromycin, clarithromycin, azithromycin	Natural and semi-synthetic forms of 14- and 16-member lactone rings (from <i>S. erythraea</i> and <i>S. ambofaciens</i>)	Aerobic and anaerobic gram-positive and gram-negative species	50 S ribosome	Protein translation (through inhibition of elongation and translocation steps) and free tRNA depletion
Streptogramins					
Protein synthesis inhibitor	Pristinamycin, quinupristin-dalfopristin	Natural and semi-synthetic forms of pristinamycin I (group B, macrolactone ringed-peptides) and pristinamycin II (group A, endolactone oxazole nucleus-bearing depsipeptides) (from <i>Streptomyces</i> spp.)	Aerobic and anaerobic gram-positive and gram-negative species ^b	50 S ribosome	Protein translation (through inhibition of initiation, elongation, and translocation steps) and free tRNA depletion
Phenicol					
Protein synthesis inhibitor	Chloramphenicol	Natural and semi-synthetic forms of dichloroacetic acid with an aromatic nucleus and aminopropanediol chain (from <i>S. venezuelae</i>)	Some gram-positive and gram-negative species, including <i>B. fragilis</i> , <i>N. meningitidis</i> , <i>H. influenzae</i> , and <i>S. pneumoniae</i>	50 S ribosome	Protein translation (through inhibition of elongation step)
Polypeptides					
Disrupts bacterial cell membrane	Polymyxin B, polymyxin E (colistin)	Contain non-protein polypeptide chains, originally from <i>B. polymyxa</i>	Only against gram-negative bacilli, particularly <i>Pseudomonas</i> spp. and <i>Acinetobacter</i> spp.	Phospholipids in cell membrane	Increases cell permeability and disrupts osmotic integrity
Lincosamides					
Protein synthesis inhibitor	Lincomycin, clindamycin	Natural and semi-synthetic forms of lincomycin originally from <i>S. lincolnensis</i>	Clindamycin broad spectrum against anaerobic gram-positive species	50 S ribosome	Prevents elongation of peptide chains by interfering with peptidyl transfer

^aDrug efficacy can vary across species range based on drug generation.

^bWhen used as a combination of pristinamycin I and pristinamycin II.

B. fragilis, *Bacillus fragilis*; *B. polymyxa*, *Bacillus polymyxa*; *C. acremonium*, *Cephalosporium acremonium*; *C. perfringens*, *Clostridium perfringens*; ETC, electron transport chain; Fe-S, iron-sulfur; *H. influenzae*, *Haemophilus influenzae*; *M. tuberculosis*, *Mycobacterium tuberculosis*; *N. meningitidis*, *Neisseria meningitidis*; *P. notatum*, *Penicillium notatum*; ROS, reactive oxygen species; *S. ambofaciens*, *Streptomyces ambofaciens*; *S. aureofaciens*, *Streptomyces aureofaciens*; *S. cattleya*, *Streptomyces cattleya*; *S. erythraea*, *Saccharopolyspora erythraea*; *S. lincolnensis*, *Streptomyces lincolnensis*; *S. mediterranei*, *Streptomyces mediterranei*; *S. pneumoniae*, *Streptococcus pneumoniae*; *S. rimosus*, *Streptomyces rimosus*; *S. roseosporus*, *Streptomyces roseosporus*; *S. venezuelae*, *Streptomyces venezuelae*; TCA, tricarboxylic acid; TMP/SMX, trimethoprim/sulfamethoxazole; TCA cycle, the citric acid cycle; tRNA, transfer RNA.

Fig. 12.1 Primary sites of antibacterial action for major classes of antimicrobial agents. *DHFA*, Dihydrofolic acid; *DNA*, deoxyribonucleic acid; *mRNA*, messenger RNA; *PABA*, *p*-aminobenzoic acid; *THFA*, tetrahydrofolic acid.

Fig. 12.2 The cell envelope structure of a gram-positive (*left*) and a gram-negative (*right*) bacterium.

Fig. 12.3). This precursor molecule elongates peptidoglycan by performing transglycosylation of the glycan strands; elongation of the peptide strands occurs by transpeptidation.

The **β -lactam antibiotics** include the penicillins, cephalosporins, penems, cephems, carbapenems, and monobactams. These closely related compounds act by forming covalent complexes with enzymes that generate the mature peptidoglycan molecule. Because the functions of these enzymes were studied in the context of penicillin binding and resistance, they are known collectively as **penicillin-binding proteins (PBPs)**. PBPs are bifunctional transpeptidase-transglycosylase enzymes that mediate peptidoglycan cross-linking (**Table 12.2**).

The active moiety of β -lactam is the four-member **β -lactam ring** (**Fig. 12.4**). This four-member ring functions as a structural analogue of the normal substrate acyl-D-Ala-D-Ala.

The structural similarity between β -lactam antibiotics and D-Ala-D-Ala facilitates their binding to the active site of PBPs and inhibition of the transpeptidation reaction, resulting in bacterial lysis and cell death. The effects of drug binding on cell growth differ, depending on the agent and PBP involved. Some inhibit cell division, leading to long filamentous forms, whereas others lead to the formation of cell wall-deficient types that readily lyse under high osmotic pressure. In gram-negative cells, the β -lactams must pass through outer membrane porin channels to reach the target PBPs.

The narrow- to broad-spectrum antimicrobial activity, safety, and efficacy of β -lactam antibiotics are typically enhanced by the modification of moieties attached to the penicillin and cephalosporin ring structures (see **Fig. 12.4**). Carbapenems have the broadest spectrum of activity within

the β -lactam class, have a high affinity for PBPs, and are stable against most Ambler class A, C, and D β -lactamases. Doripenem, a carbapenem used for the treatment of complicated urinary tract and intraabdominal infections, is unique in that it has activity against gram-positive and gram-negative bacteria, including *P. aeruginosa*. Although older cephalosporins do not inhibit the PBPs of *P. aeruginosa*, newer ones such as ceftolozane/tazobactam (trade name Zerbaxa) inhibit PBP1b, PBP1c, and PBP3 of *P. aeruginosa*.

Table 12.3 presents a different β -lactamase classification than the Ambler classification that is based on the functional properties of enzymes (i.e., the substrate and inhibitor profiles). This scheme is referred to as the

Fig. 12.3 The structure of the peptidoglycan layer in the cell wall of *Escherichia coli*. The amino acids in the cross-linking tetrapeptides may differ among species. NAG, N-acetyl-D-glucosamine; NAM, N-acetyl-D-muramic acid. (From Neidhardt, F. C., et al. [1990]. *Physiology of the bacterial cell: a molecular approach*. Sunderland, MA: Sinauer Associates.)

Bush-Jacoby-Medeiros classification. These schemes are for convenience, and one classification is no more correct than the other.

Glycopeptides, such as vancomycin, dalbavancin, teicoplanin, and the investigational drugs oritavancin and telavancin, act by binding to the terminal D-Ala-D-Ala of the pentapeptidyl-glycosyl peptidoglycan intermediates (see Fig. 12.3). This prevents their incorporation into the peptidoglycan chain by blocking the transpeptidation step in cell wall biosynthesis. Glycopeptides bind to the substrate of the transpeptidation enzyme, whereas penicillins bind to the enzyme mediating the transpeptidation reaction. Because they cannot cross the outer membrane of gram-negative bacteria, the clinical spectrum of glycopeptides is limited to gram-positive microorganisms; thus they are mainly used in the United States to treat aerobic clinical infections caused by staphylococci, streptococci, and enterococci.

Fig. 12.4 Chemical structures of major classes of β -lactam antibiotics.

Table 12.2 Penicillins, cepheids, carbapenems, and monobactam β -lactam antibiotics			
Class	Subclass	Category	Adopted name in the United States
Penicillins		Narrow spectrum and penicillinase—sensitive	Penicillin G, penicillin V
		Penicillinase—sensitive and semi-synthetic	Amoxicillin, ampicillin
		Penicillinase—resistant and semi-synthetic	Nafcillin, oxacillin
	Aminopenicillin	Extended spectrum and semi-synthetic	Amoxicillin, ampicillin
	Carboxypenicillin	Extended spectrum and semi-synthetic	Ticarcillin, carbenicillin
Cepheids	Ureidopenicillin	Extended spectrum and semi-synthetic	Piperacillin
	Cephalosporin I	Narrow-spectrum, first generation	Cephalothin, cefazolin, cephalexin
	Cephalosporin II	Expanded-spectrum, second generation	Cefonicid, cefuroxime,
	Cephalosporin III	Broad-spectrum, third generation	Cefoperazone, ceftazidime
	Cephalosporin IV	Extended-spectrum, fourth generation	Cefepime, ceftoxitin
	Carbacephem	Broad spectrum	Loracarbef
Carbapenems		Broad spectrum	Doripenem, ertapenem, imipenem, meropenem
Monobactams		Narrow-spectrum	Aztreonam

Table 12.3 Current major β -lactamase functional and molecular classification schemes

Bush-Jacoby group (2010)	Bush-Jacoby-Medeiros group (1995)	Molecular class (subclass)	Distinctive substrate(s)	Inhibited by		Defining characteristic(s)	Representative enzyme(s)
				CA or TZB	EDTA		
1	1	C	Cephalosporins	No	No	Greater hydrolysis of cephalosporins than benzylpenicillin; hydrolyzes cephamycins	<i>E. coli</i> AmpC, P99, ACT-1, CMY-2, FOX-1, MIR-1
1e	NI	C	Cephalosporins	No	No	Increased hydrolysis of ceftazidime and often other oxyimino- β -lactams	GC1, CMY-37
2a	2a	A	Penicillins	Yes	No	Greater hydrolysis of benzylpenicillin than cephalosporins	PC1
2b	2b	A	Penicillins, early cephalosporins	Yes	No	Similar hydrolysis of benzylpenicillin and cephalosporins	TEM-1, TEM-2, SHV-1
2be	2be	A	Extended-spectrum cephalosporins, monobactams	Yes	No	Increased hydrolysis of oxyimino- β -lactams (cefotaxime, ceftazidime, ceftriaxone, cefepime, aztreonam)	TEM-3, SHV-2, CTX-M-15, PER-1, VEB-1
2br	2br	A	Penicillins	No	No	Resistance to CA, sulbactam, and TZB	TEM-30, SHV-10
2ber	NI	A	Extended-spectrum cephalosporins, monobactams	No	No	Increased hydrolysis of oxyimino- β -lactams combined with resistance to CA, sulbactam, and TZB	TEM-50
2c	2c	A	Carbenicillin	Yes	No	Increased hydrolysis of carbenicillin	PSE-1, CARB-3
2ce	NI	A	Carbenicillin, cefepime	Yes	No	Increased hydrolysis of carbenicillin, cefepime, and cefpirome	RTG-4
2d	2d	D	Cloxacillin	Variable	No	Increased hydrolysis of cloxacillin or oxacillin	OXA-1, OXA-10
2de	NI	D	Extended-spectrum cephalosporins	Variable	No	Hydrolyzes cloxacillin or oxacillin and oxyimino- β -lactams	OXA-11, OXA-15
2df	NI	D	Carbapenems	Variable	No	Hydrolyzes cloxacillin or oxacillin and carbapenems	OXA-23, OXA-48
2e	2e	A	Extended-spectrum cephalosporins	Yes	No	Hydrolyzes cephalosporins; inhibited by CA but not aztreonam	CepA
2f	2f	A	Carbapenems	Variable	No	Increased hydrolysis of carbapenems, oxyimino- β -lactams, cephamycins	KPC-2, IMI-1, SME-1
3a	3	B (B1)	Carbapenems	No	Yes	Broad-spectrum hydrolysis, including carbapenems but not monobactams	IMP-1, VIM-1, CcrA, IND-1
		B (B3)					L1, CAU-1, GOB-1, FEZ-1
3b	3	B (B2)	Carbapenems	No	Yes	Preferential hydrolysis of carbapenems	CphA, Sfh-1
NI	4	Unknown					

CA, Clavulanic acid; EDTA, ethylenediaminetetraacetic acid; NI, not included; TZB, tazobactam.

From Bush, K., & Jacoby, G. A. (2010). Updated functional classification of beta-lactamases. *Antimicrobial Agents and Chemotherapy*, 54(3):969–976; and Bush, K., Jacoby, G. A., & Medeiros, A. A. (1995). A functional classification scheme for β -lactamases and its correlation with molecular structure. *Antimicrobial Agents and Chemotherapy*, 39:1211–1233.

Inhibition of folate synthesis

The folic acid pathway provides the essential precursor molecules needed for DNA biosynthesis in bacteria. The pathway is mediated by two key enzymes, dihydropteroate synthase and dihydrofolate reductase, which mediate the formation of tetrahydrofolate (THF) from dihydrofolate (Fig. 12.5). **Sulfamethoxazole** (SMZ) blocks the step leading to the formation of 7,8-dihydropteroate by competitively inhibiting the binding of the structural analogue aminobenzoic acid with dihydropteroate synthase. **Trimethoprim** (TMP) blocks the step leading to the formation of THF by preventing the dihydrofolate reductase-mediated recycling of folate coenzymes. Unlike other members of the current antimicrobial classes, SMZ and TMP are completely synthetic molecules that have never existed in nature. The spectrum of activity of folate pathway inhibitors, especially when provided in combination, provides activity against the Enterobacterales that cause urinary tract infections. TMP and SMZ are often used together under the brand names Bactrim and Septra.

Interference with DNA replication

The prokaryotic cell cycle consists of **DNA replication** followed immediately by cell division. In microorganisms such as *Escherichia coli*, which divide in approximately 30 minutes under ideal growth conditions, DNA replication must be initiated and completed to ensure that each DNA duplex is delivered to each daughter cell. Enzymes necessary for DNA replication include topoisomerases I, II, III, and IV. **Quinolones** are antibacterial drugs that affect DNA

replication by targeting topoisomerases II (DNA gyrase) and IV, enzymes considered important in controlling DNA topology, replication, and decatenation at the end of the bacterial DNA replicative cycle.

DNA gyrase and topoisomerase IV are tetrameric molecules composed of dimeric A and B subunits. The subunits of DNA gyrase are encoded by *gyrA* and *gyrB*, whereas the subunits of topoisomerase IV are encoded by *parC* and *parE*. The tetramers of DNA gyrase and topoisomerase IV are highly homologous, with *gyrA* homologous to *parC* and *gyrB* homologous to *parE*. Interestingly, the targets of quinolones appear to be selective, targeting DNA gyrase in gram-negative bacteria and topoisomerase IV in gram-positive bacteria, but newer quinolones appear to have a high affinity for both targets. Analyses of mechanisms of action suggest that quinolones interact with DNA gyrase–DNA complexes and topoisomerase IV–DNA complexes to trap the enzymes as stabilized reaction intermediates, leading to inhibition of DNA replication, which immediately leads to bacteriostasis and eventual cell death.

The quinolones and fluoroquinolones are used to treat the Enterobacterales, pseudomonads, *Neisseria*, and other gram-negative bacteria as well as staphylococci, enterococci, and streptococcal species other than *Streptococcus pneumoniae*. More so than some other drug classes, the rate of fluoroquinolone resistance has been increasing. Fluoroquinolone resistance correlates with the use of the agent in the human population and is mainly caused by chromosomal mutations.

Interference with DNA transcription

DNA transcription is the process whereby a template DNA strand is copied into a functional RNA sequence, resulting in mature mRNA or structural RNA. The **transcription** of DNA into RNA is mediated by RNA polymerase; bacterial RNA polymerase is a core tetramer composed of an α subunit, two β subunits ($\beta\beta'$), a γ subunit, and a dissociable σ subunit that controls the transcription of specific gene classes.

Rifampin, a synthetic derivative of rifamycin B, targets DNA transcription. The principle therapeutic use of rifampin is in combination with other antibacterial classes to treat *Mycobacterium tuberculosis* infection. The target of rifampin in *M. tuberculosis* is the RNA polymerase β subunit at an allosteric site, with the subsequent blocking of RNA chain elongation. As a result, RNA transcription is aborted at the initiation step. Less commonly, rifampin is used to treat aerobic species including staphylococci, enterococci, *Haemophilus* spp., and *S. pneumoniae*. Rifamycins in combination with ciprofloxacin and clindamycin are reported to be useful for the treatment of bacterial infections relevant to biowarfare or bioterrorism, such as inhalational anthrax.

Interference of mRNA translation

The cellular machinery of living organisms decodes mRNA into functional protein, a process called **mRNA translation**. Protein biosynthesis requires the sequential binding of the 30S and 50S ribosomal subunits to mRNA, leading to translation of the genetic message. The initiation phase commences with initiation factors, proteins that bind to the 30S subunit, and the initiator transfer RNA (tRNA), formylmethionyl-tRNA, which binds to the P site of the 30S ribosomal subunit.

Fig. 12.5 Sites of action of sulfonamides and trimethoprim and their effects on the synthesis of essential amino acids and nucleic acids.

This 30S subunit helps the bound initiator tRNA scan and find the start codon on mRNA. Next, the 50S subunit binds to form the preinitiation complex. The codon immediately following the initiation codon dictates binding of the next tRNA to the ribosomal A site.

Because protein synthesis is central to cellular function and bacterial ribosomes differ from eucaryote ribosomes, it is an excellent target for antibacterial drug product development. Thus the bacterial ribosome is a primary target of numerous drugs, with some targeting the 30S ribosomal subunit (e.g., aminoglycosides, tetracyclines, glycylcyclines) and others targeting the 50S ribosomal subunit (e.g., macrolides, lincosamides, chloramphenicol, oxazolidinones, streptogramins; see Fig. 12.1). Among ribosome inhibitors, naturally derived aminoglycosides are the only class that is broadly bactericidal. Macrolides, streptogramins, spectinomycin, tetracyclines, and chloramphenicol are typically bacteriostatic; however, they can be bactericidal in a species-specific manner (e.g., chloramphenicol has been shown to kill *S. pneumoniae*). This species-specific bactericidal effect probably involves sequence differences among bacterial species in the variable regions of the highly conserved ribosomal RNA (rRNA).

Aminoglycosides are cationic carbohydrate-containing molecules, and their positive charge provides the basis for their interaction with a specific region of the 16S RNA in the 30S ribosomal subunit. The 30S subunit provides a high-affinity docking site mediated by hydrogen bonding to the various substituents in the aminoglycoside cyclitol ring. Binding of aminoglycosides to the A binding site on the 30S subunit prevents the docking of aminoacyl-tRNA, resulting in mistranslation and subsequent production of aberrant proteins. The incorporation of aberrant proteins into the cell wall also results in cell leakage and enhanced cellular penetration of additional antimicrobial agents. To penetrate the bacterial inner membrane and reach the target, an aerobic energy-yielding step is necessary. The requirement for an aerobic environment for activation explains the aminoglycosides' lack of activity against anaerobic bacteria.

Spectinomycin is a disaccharide aminocyclitol antibiotic that is produced by *Streptomyces spectabilis* and is active against many gram-negative bacterial species. It binds to the 16S rRNA component of the 30S ribosomal subunit and interferes with the binding stability of peptidyl-tRNA to the ribosome by inhibiting elongation factor-catalyzed translocation, but it does not cause protein mistranslation.

Tetracycline compounds are members of the polyketide class of antibacterials and are represented by tetracycline, doxycycline, and minocycline. As shown in Fig. 12.1, the tetracyclines target the 30S ribosomal subunit. Tetracyclines reversibly inhibit protein synthesis by binding to 16S rRNA near the aminoacyl-tRNA acceptor site, thus inhibiting the rotation of bound tRNA into the A site during translation. This physical blocking by tetracycline results in the premature release of tRNA and termination of peptide bond formation. The tetracyclines are broad-spectrum, bacteriostatic drugs.

Macrolides, such as erythromycin, clarithromycin, and azithromycin, target the 50S subunit specifically by binding to the peptidyltransferase cavity in the proximity of the A and P loops, near adenine 2058 of 23S rRNA. By blocking the exit tunnel of the elongating peptides, premature release of peptidyl-tRNA intermediates occurs, and polypeptide translation ceases. Macrolides also prevent assembly of the

50S ribosomal subunit by binding to 23S rRNA. As shown in Fig. 12.1, lincosamides (clindamycin) and chloramphenicol also target the 50S ribosomal subunit, thus inhibiting mRNA translation and, subsequently, protein synthesis. Macrolides and tetracyclines allow initiation and mRNA translation to begin but act by inhibiting peptide elongation.

Ketolides share many of the characteristics of the advanced macrolides. They are semi-synthetic derivatives of 14-member-ring macrolides and have a carbonyl group at the C-3 position, which allows them to be active against macrolide-resistant strains, increasing their activity against gram-positive cocci. Telithromycin was the first member of this class to be approved by the FDA for clinical use for the treatment of community-acquired pneumonia. The mechanism of action is very similar to that of erythromycin. The ketolides bind close to the peptidyltransferase site of the 50S subunit of the bacterial ribosome, inhibiting RNA-dependent protein synthesis. Ketolides bypass macrolide-resistant mechanisms by increasing ribosome binding affinity, especially binding to domain II of the 23S rRNA, and evading macrolide efflux mechanisms.

The most recently approved classes of antimicrobial agents targeting protein synthesis are the oxazolidinones, represented by linezolid; the streptogramins, represented by quinupristin-dalfopristin; and the glycylcyclines, represented by tigecycline.

Oxazolidinones have activity against gram-positive bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), *S. pneumoniae*, and *M. tuberculosis*. **Linezolid** is thought to bind to the 50S ribosomal subunit, preventing formation of the preinitiation complex with the 30S ribosomal subunit containing bound initiation factors. The 50S ribosomal target appears to be the ribosomal P site in the peptidyltransferase center, and by blocking this site, the first peptide-forming step is prevented, and protein synthesis is terminated. Linezolid differs from other protein synthesis inhibitors by blocking the initiation step and translocation of peptidyl-tRNA from the A site to the P site, whereas macrolides and tetracyclines block peptide chain elongation.

Glycylcyclines, represented by tigecycline, are derivatives of the tetracycline class and carry a glycylamido moiety attached to the 9-position of minocycline. **Tigecycline** reversibly inhibits protein translation in bacteria by binding to the 30S ribosomal subunit and blocking entry of aminoacyl-tRNA molecules onto the A site of the ribosome, thus preventing the incorporation of amino acid residues into elongating peptide chains. Tigecycline has a stronger binding affinity for the 30S ribosomal subunit than tetracycline and has more potent activity against tetracycline-resistant organisms with efflux and ribosomal protection mechanisms of resistance. Tigecycline has a wide spectrum of activity against many gram-positive and gram-negative organisms as well as some mycobacteria and anaerobic pathogens.

Streptogramin antibiotics are composed of a mixture of two classes of distinct molecules designated *streptogramin A* and *streptogramin B*. Dalfopristin-quinupristin is a combination of these two streptogramins in a ratio of 70:30. Dalfopristin is a polyunsaturated macrolactone classified as a type A streptogramin, and quinupristin is a peptide macrolactone classified as a type B streptogramin. Streptogramins disrupt translation of mRNA into protein by binding to the peptidyltransferase domain of the bacterial ribosome. Dalfopristin interferes with the elongation

of the polypeptide chain by preventing binding of aminoacyl-tRNA to the ribosome and the formation of peptide bonds. Quinupristin stimulates the dissociation of the peptidyl-tRNA and is thought to interfere with the release of the completed polypeptide by blocking the exit tunnel through which it normally leaves the ribosome. Dalfopristin and quinupristin act synergistically because of the enhanced affinity of quinupristin for the ribosome. Dalfopristin induces a conformational change such that quinupristin binds with greater affinity. The natural streptogramins are produced as mixtures of dalfopristin and quinupristin; their combination is a more potent antibacterial agent than either compound alone.

Combined mechanisms of action

Although antibacterial agents may have several mechanisms of action, one mechanism generally predominates. However, newer antimicrobials have several main mechanisms of action. Such an agent is oritavancin, a semi-synthetic lipoglycopeptide with three main mechanisms of action: (1) inhibition of the transglycosylation (polymerization) step of cell wall biosynthesis, (2) inhibition of the transpeptidation (cross-linking) step of cell wall biosynthesis, and (3) disruption of bacterial membrane integrity. All or any one of these mechanisms can be bacteriocidal. Structurally, oritavancin resembles vancomycin and is most active against gram-positive bacteria.

Mechanisms of antimicrobial resistance

Bacteria use two strategies to avoid being killed by antimicrobial agents: *tolerance* and *resistance*. Tolerance is a property of dormant, nongrowing bacteria (persisters) in which drug targets are inactive, allowing bacteria to avoid damage and survive. **Persister cells** are subpopulations of bacteria deep in a biofilm (discussed later) that can differentiate into a phenotypically resistant state (e.g., slow-growing or nongrowing bacteria). Mechanisms of persister formation include a decrease in adenosine triphosphate (ATP) concentration and toxins that stop essential cellular processes. Cells also contain anti-toxins that can block the action of the toxin allowing growth to resume. Persister bacteria have been shown to carry mutations in promoter genes. When conditions are favorable for growth (e.g., no antimicrobial is present), these bacteria will resume growth. Generally, the persister bacteria that resume growth are resistant to the drug to which they were originally exposed because of mutations that have occurred.

Resistance to antimicrobial agents is conveniently divided into mechanisms that are **intrinsic** or acquired resistance. Intrinsic mechanisms of resistance are an innate characteristic of the microorganism and are transmitted to progeny vertically. Such resistance is considered a natural and consistently inherited characteristic of a particular microbial group, genus, or species. Therefore this resistance is predictable once the organism is identified. For example, some gram-negative bacteria are intrinsically resistant to the activity of macrolides because these agents are too large to traverse the cell wall (impermeability).

Acquired mechanisms of resistance are caused by changes in the usual genetic makeup of a microorganism, leading to altered cellular physiology and structure. Unlike intrinsic resistance, acquired resistance can be a trait associated with only some strains of a particular species. Thus the presence of this type of resistance in any of the isolates is unpredictable. The gene changes or exchanges that result from acquired resistance are usually caused by genetic mutation(s), acquisition of genes from other organisms via gene transfer mechanisms, or a combination of mutational and gene transfer events. Where feasible, this section will use members of the antimicrobial classes discussed earlier to exemplify intrinsic or acquired mechanisms of resistance.

Case check 12.2

The discovery of antibacterial agents was a turning point in human history. Antimicrobials have revolutionized medicine in many respects and saved millions of lives. Unfortunately, antimicrobial resistance is an outcome of natural selection, and the use of these drugs has been accompanied by the rapid development of resistance. Currently, over 100 antimicrobials have been approved for use in clinical medicine; however, resistance has developed to each drug, with different times and frequencies, in various bacterial genera. The MDR bacteria causing the infection in the Case in Point likely underwent natural selection because of repeated exposure to numerous antimicrobial agents.

The most common resistance mechanisms bacteria use include enzymatic degradation or alteration of the drug, mutation in the antimicrobial target site, decreased cell wall permeability to antimicrobials, and active efflux of the antimicrobial across the cell membrane. Inappropriate use of antimicrobials in human and veterinary medicine, animal husbandry, and agriculture over many years has resulted in unremitting selection pressure to accelerate resistance development in microbial populations.

Antimicrobial resistance is a significant public health concern. Resistance to commonly used antimicrobials is now encountered frequently, and the emergence of MDR bacteria poses greater challenges to the treatment of infections. Infection with MDR bacteria can cause treatment failure, increase the burden of illness, and result in higher mortality as well as financial burden.

Origins of antimicrobial resistance

Resistance genes and transfer mechanisms existed long before the use of modern therapeutic antimicrobials. For example, MDR bacteria estimated at being more than 2000 years of age were recovered from glacial samples obtained from the Canadian Arctic Archipelago, whereas another study detected β -lactamases from a metagenomic library of cold-seep sediments of deep-sea Edison Seamount (near Papua New Guinea) that were estimated to be about 10,000 years of age. In addition, plasmids found in gram-negative bacteria that were isolated before antimicrobials were introduced into clinical practice resemble currently described plasmids, except that the early isolates did not possess any resistance genes. **Plasmids** are small circular DNA fragments found outside the chromosome.

Resistance to natural antimicrobial agents, synthetic derivatives, and completely synthetic antimicrobials was observed in a collection of soil-dwelling actinomycetes, with some displaying resistance mechanisms not traditionally observed in clinical bacterial pathogens. Most soil isolates display resistance to at least 6 different antimicrobial agents and, in some cases, as many as 20. The use of novel resistance mechanisms by these organisms, coupled with the fact that these soil microbes are not as intensively exposed to antimicrobial selective pressures as the clinical pathogens, emphasize that resistance is a natural part of microbial ecosystems and highlights the evolutionary possibilities for novel antimicrobial resistance determinants.

If bacterial resistance to antimicrobial agents is not a new phenomenon, where did it originate? One popular theory is that antimicrobial resistance mechanisms arose within antibiotic-producing microorganisms as a mechanism to protect them against the action of their own antibiotic (autotoxicity). This has been substantiated by the finding of aminoglycoside-modifying enzymes in aminoglycoside-producing organisms that display marked homology to modifying enzymes found in aminoglycoside-resistant bacteria. Also, the essential genetic determinants associated with resistance to vancomycin, *vanA*, *vanH*, and *vanX*, appear to be very similar to the self-protection mechanism used in the vancomycin-producing *Actinomyces* strains. In addition, some antibiotic preparations used for humans and animals were found to be contaminated with chromosomal DNA of an antibiotic-producing organism, including antimicrobial resistance gene sequences. It has been postulated that the presence of DNA encoding antimicrobial resistance in antibiotic preparations has been a factor in the rapid development of multiple antibiotic resistance by providing the resistance sequences that can be incorporated by the pathogen.

Intrinsic mechanisms of resistance

Intrinsic resistance is the innate ability of a bacterial species to resist the activity of a particular antimicrobial agent through inherent structural or functional characteristics, allowing tolerance of a particular drug or antimicrobial class. Such natural resistance can be caused by (1) lack of affinity of the drug for the bacterial target, (2) inability of the drug to enter the bacterial cell, (3) removal of the drug by chromosomally encoded efflux pumps (constitutive drug efflux), and (4) innate production of enzymes that inactivate the drug. Bacteria differ widely in cell wall composition, thus their intrinsic susceptibility or resistance to antimicrobial agents depends on the hydrophobic or hydrophilic nature of the drug and on the impermeability of the cell wall to the drug. Intrinsic resistance mediated by impermeability is exemplified by cell wall composition, efflux, and biofilm (see Chapter 31) formation.

Biofilms

Biofilms are sessile communities of microorganisms that are irreversibly attached to a solid surface and are embedded in an exopolysaccharide matrix. Biofilms play an important role in animal infections, and they are a cause for concern because the bacteria in biofilms are highly resistant to antimicrobial agents and host defenses. The mechanisms of biofilm-associated

antimicrobial resistance are multifactorial, involving a complex system of cell-to-cell chemical communication that varies from organism to organism. Thus resistance exhibited by bacteria when they grow in biofilms is not attributed to typically acquired genetic mechanisms (e.g., gene mutation, mobile acquisition), but is instead determined by the chemical and physical characteristics of biofilm formation.

The genetic mechanisms of biofilm antimicrobial resistance appear to fall into two general classes: innate resistance factors and induced resistance factors. Innate mechanisms are activated as part of the biofilm developmental pathway; these factors are integral parts of biofilm structure and physiology (e.g., decreased penetration of antimicrobial agents into the biofilm, decreased oxygen and nutrient availability accompanied by altered metabolic activity, formation of persister cells).

Induced resistance factors include those resulting from induction by the antimicrobial agent itself, resulting in differential resistance gene expression throughout the biofilm community. Biofilm antimicrobial resistance is a complex combination of innate anabolic metabolism and induced genetic mechanisms, many of which still need to be elucidated. Because of the important nature of biofilm-associated antimicrobial resistance, numerous investigators are focusing on the development of novel therapies aimed at disrupting biofilms.

Impermeability

For antimicrobials to affect internal cellular processes, they must penetrate the bacterial cell wall to reach their target. Influx of agents through the cell wall depends on the chemical nature of the agent and the structural characteristics of the cell wall (see Fig. 12.2). The intrinsic resistance of gram-negative bacteria to vancomycin is an example of their outer membrane being impermeable to the large, rigid, and hydrophobic glycopeptide molecule vancomycin. Unlike gram-negative bacteria, some gram-positive bacterial species such as *Lactobacillus* and *Leuconostoc* spp. also have intrinsic resistance to vancomycin, but this resistance is caused by the lack of an appropriate cell wall precursor target to allow vancomycin to bind and inhibit cell wall synthesis. *Enterococcus faecalis* and *Enterococcus faecium* are intrinsically resistant to low levels of penicillin because of PBPs (PBP5) with low affinity for penicillins.

In gram-negative bacteria, there are two fundamental structures of the cell wall leading to clinically relevant resistance caused by impermeability: (1) LPS composition and (2) the structure and expression of outer membrane proteins (Omps), called **porins**. Molecular analysis of gram-negative bacteria reveals that the strongly negatively charged core region of the LPS functions as a selective permeability barrier for negatively charged antimicrobial agents, resulting in decreased susceptibility to these compounds. Mutations in the O-antigen side chains of the LPS can change the shape and overall charge of the cell wall, decreasing the binding efficiency of some cationic agents. Mutations in the LPS genes have been seen in conjunction with increasing drug selective pressure. Thus, the cell wall partially accounts for the intrinsic resistance of bacteria to antimicrobial agents. It is usually only clinically significant in the context of other resistance mechanisms, such as efflux (discussed later), that work synergistically to mediate survival of the organism. For example, *P. aeruginosa* is intrinsically resistant to a wide variety of

antimicrobial agents, including β -lactams, β -lactam inhibitors, sulfonamides, trimethoprim, tetracycline, and chloramphenicol. Although this resistance has usually been attributable to a highly impermeable outer membrane, it has also been shown to result from the synergy between a unique efflux system (*MexAB-OprM*) and decreased outer membrane permeability.

Porins serve as natural outer membrane channels that permit the influx of nutrients and efflux of waste products. They also serve to restrict the influx of antimicrobial agents and maintain low intracellular concentrations. In addition, alterations leading to decreased porin production or changes in the structure of porins that reduce their affinity for a drug can alter a resistance phenotype. In *E. coli*, major Omps include OmpA, OmpC, and OmpF. These proteins function as channels through which many small molecules, such as nutrients and antimicrobial agents, diffuse. Alteration or loss of OmpC and OmpF has been linked to decreased susceptibility to several antimicrobial agents, especially the carbapenems. Healthcare-associated pathogens showing a decrease or loss of porin synthesis are often observed in combination with other resistance mechanisms, resulting in MDR pathogens.

Efflux

Intrinsic resistance of bacteria to certain antimicrobials is caused by the activity of efflux systems and impermeability (Fig. 12.6). **Efflux pumps** are found in gram-positive and gram-negative bacteria and function as transporter proteins for the export of toxic substances and antimicrobial agents from the interior of the cell to the external environment. Efflux pumps are naturally occurring and are present in susceptible and resistant microorganisms. Efflux mechanisms can confer resistance to a particular antimicrobial agent, a class of agents, or several unrelated antimicrobials resulting in MDR.

Based on the amino acid sequence and energy source used to export their substrates, bacterial efflux transporters are classified into five major superfamilies: (1) the major facilitator superfamily (MFS), (2) the resistance nodulation cell division (RND) superfamily, (3) the small MDR family, (4) the ATP-binding cassette (ABC) superfamily, and (5) the

multidrug and toxic effects family. Of these, only the transporters in the ABC superfamily are primary transporters and hydrolyze ATP by ATPases to provide the energy required for active transport of antimicrobial agents and other toxic molecules. The rest of the families are secondary transporters that use a proton or sodium gradient as an energy source. The MFS dominates in gram-positive bacteria, whereas the RND superfamily is unique to gram-negative bacteria. The intrinsic efflux mechanism of resistance is chromosomally located and is activated by environmental signals or by mutation in regulatory genes.

In the RND superfamily, the *mexAB-oprM* operon in *P. aeruginosa* regulates porin and pump genes. This genetic locus plays a major role in the intrinsic resistance of pseudomonads and is a primary reason why infections caused by members of this genus are difficult to treat. This three-component efflux pump provides an exit portal for numerous agents, including quinolones, tetracyclines, macrolides, chloramphenicol, β -lactams, and meropenem, but not imipenem. The emerging resistance to imipenem in *P. aeruginosa* has been associated with the loss of the specific channel OproD, which facilitates the uptake of imipenem.

Bacterial cross-resistance to multiple antimicrobials can be mediated by efflux pumps capable of using multiple substrates. Exposure of a microorganism possessing an efflux pump to any one substrate belonging to a similar or different substrate profile used by that pump results in overexpression and consequent cross-resistance to all other substrates. Antimicrobials are no exception; in the *mexAB* system of *P. aeruginosa*, mutants that overproduce MexAB are less susceptible to fluoroquinolones, β -lactams, chloramphenicol, trimethoprim, and the antiseptic triclosan.

Efflux-mediated resistance to the oxazolidinones and streptogramins has been identified in gram-negative bacteria and *E. faecalis*, respectively. *E. faecalis* appears to be intrinsically resistant to dalbavancin, a streptogramin component of quinupristin-dalbavancin. The efflux mechanism designated *lsa* for *lincosamide and streptogramin A resistance* shows similarities to members of the superfamily of transporter proteins known as *ABC transporters* and influences resistance to quinupristin-dalbavancin and clindamycin. Most bacteria possess numerous efflux pumps; however, only a few per species appear to contribute resistance to antimicrobial agents used in clinical practice.

Enzymatic inactivation

Bacteria can produce enzymes that destroy the antimicrobial agents before they are able to reach their targets. Enzymatic inactivation of antimicrobial agents is one of the most intrinsic and acquired resistance mechanisms for β -lactam antibiotics, the class of agents most used to treat bacterial infections. They consist of four major groups: penicillins, cephalosporins, monobactams, and carbapenems (see Table 12.2) and differ from each other in their basic ring structure and moieties attached to the rings (see Fig. 12.4). All four groups have a four-member β -lactam ring susceptible to the hydrolytic activity of β -lactamases, the most widespread mechanism of bacterial resistance to this class of antibiotics (Fig. 12.7). β -Lactamases selectively hydrolyze the β -lactam ring to form the microbiologically inactive penicilloic acid. Currently, more than 1000 β -lactam resistance genes have been identified.

Fig. 12.6 Active efflux in gram-negative bacteria mediated by transmembrane proteins located in cytoplasmic and outer membranes. *ABC ATPase*, ATP-binding cassette family pumps; H^+ , efflux pumps driven by proton motive force mediated by the counterflow of protons; *NT*, nutrient transport; *TetA*, tetracycline-specific transporter pump.

Fig. 12.7 β -Lactamase hydrolyzes the β -lactam ring portion of the penicillin molecule. The hydrolysis results in the formation of penicilloic acid, which does not have antibacterial activity.

β -Lactamases hydrolyze β -lactam antibiotics using two distinct mechanisms: a metallo-based mechanism and a serine-based mechanism. They are typically grouped into four classes, A to D, based on amino acid sequence similarity. Class A, C, and D enzymes use serine for β -lactam hydrolysis, whereas class B metalloenzymes require divalent zinc ions for substrate hydrolysis (see Table 12.3).

β -Lactam antibiotics act by binding to PBPs, bifunctional transglycosylases-transpeptidases responsible for the cross-linking (polymerization) of glycan strands (transglycosylation) and cross-linking of stem (backbone) peptide strands (transpeptidation). The similarities of class A, C, and D β -lactamases to mechanistic and architectural structures of PBPs suggest that the serine-based enzymes evolved from PBPs. Because of their structural similarity to PBPs, β -lactamases can serve as receptors for β -lactam antibiotics entering the cell. It is the binding equilibrium between PBP, β -lactamases, and the β -lactam antibiotic that determines the fate and ultimate survival of the microorganism. In addition, the observation that β -lactamases compete with PBPs for the antibiotic leads to the logical conclusion that the development of structural analogues of the β -lactam that bind the β -lactamase would enhance the activity of the β -lactam antibiotic. This observation led to the development of the **β -lactamase inhibitors (BLIs) clavulanic acid, sulbactam, and tazobactam**. The BLIs are structural analogues of the β -lactam antibiotics and function as substrates for β -lactamase, thus reducing their detrimental effects on the β -lactam antibiotic. When used jointly with β -lactam antibiotics, these inhibitors enhance the *in vitro* microbiological and clinical activity of the antibiotic.

Class A and C β -lactamases are considered the most clinically important, with class A enzymes primarily found on plasmids and constitutively expressed; class C enzymes are usually chromosomally located and inducible by exposure to β -lactams. In gram-negative bacteria, the β -lactamases are localized to the periplasmic space, where they act on incoming β -lactam antibiotics. In gram-positive bacteria, β -lactamases are secreted as exoenzymes and offer less protection to the microorganism. Almost all gram-negative bacteria mediate intrinsic (chromosomal) resistance by the enzymatic inactivation of penicillin class antibiotics exemplified by the class C β -lactamases. For example, *Citrobacter freundii*, *Klebsiella aerogenes*, and *P. aeruginosa* are clinically important healthcare-associated pathogens encoding chromosomal versions of class C β -lactamases.

Most class B metallo-dependent enzymes are chromosomally encoded cephalosporinases, and their expression can be constitutive or inducible. These β -lactamases are usually expressed in clinically important healthcare-associated pathogens such as *Stenotrophomonas maltophilia*, *Klebsiella pneumoniae*, and *P. aeruginosa*. Although the genes that regulate the production of these enzymes are commonly found on the chromosome, they can escape to plasmids and become transmissible, as has occurred for the class C enzyme encoded by *bla*CMY, which is widespread in enteric bacteria.

Acquired mechanisms of resistance

As noted earlier, the resistance mechanisms and genes that mediate resistance have presumably evolved in organisms that produce antimicrobial agents, so the agents are not effective against the producing organism. Furthermore, organisms that coevolved with antimicrobial-producing organisms may have acquired new functions in normal housekeeping genes to help detoxify antimicrobials. Thus by the process of natural selection, target organisms can acquire, evolve, and disseminate resistance determinants and use multiple combinations of intrinsic and acquired drug resistance strategies to survive toxic environments. This section focuses on acquired mechanisms such as efflux, modification of existing antimicrobial targets, acquisition of new targets, and production of enzymes that inactivate the antimicrobial.

Efflux

Although efflux plays a major role in intrinsic resistance, changes in the cell wall proteins can also result in novel acquired traits. In addition, some efflux pump genes have translocated to plasmids, which can be acquired by horizontal gene exchange. In general, multidrug efflux genes are broadly conserved in bacteria and are chromosome-encoded. On the other hand, drug-specific efflux genes are generally encoded by plasmids, so their acquisition is compounded by their association with MDR. An efflux pump encoded by the *mef* gene in *Streptococcus* is an example of an acquired macrolide resistance. The genetic element carrying *mefA* appears to be widely disseminated in *S. pneumoniae* and is transferable to other streptococcal species and other genera. *S. pneumoniae* isolates with efflux resistance are susceptible to clindamycin and usually have erythromycin minimum inhibitory concentrations (MICs) ranging from 1 to 16 $\mu\text{g/mL}$. Because the *mef*

phenotype demonstrates resistance to erythromycin but susceptibility to clindamycin, surveillance studies monitoring *S. pneumoniae* susceptibility patterns of erythromycin and clindamycin have revealed that the most prevalent mechanism of macrolide resistance in the United States is efflux mediated.

Currently, numerous plasmid-encoded acquired efflux genes that confer resistance to different antimicrobial agents have been detected in a variety of organisms. For example, plasmid-encoded tetracycline resistance efflux genes *Tet* (A), *Tet* (B), *Tet* (C), *Tet* (D), *Tet* (E), *Tet* (G), *Tet* (H), *Tet* (J), *Tet* (K), *Tet* (L), *Tet* (Y), *Tet* (Z), *Tet* (30), and *Tet* (39) have been detected in many gram-negative bacteria and attribute to most resistance phenotypes encountered in nature.

Target site modification

Modification of a target can reduce the binding affinity of the antimicrobial agent for the target. Modification of target sites occurs primarily by chromosomal mutation, as observed with the quinolone and oxazolidinone antimicrobials, and by enzymatic alteration of macrolide, glycopeptide, and β -lactam antibiotic target sites.

Chromosomal mutation

Quinolones target DNA gyrase and topoisomerase IV, inhibiting DNA synthesis. Although plasmid-mediated quinolone resistance genes (termed *qnr*) exist, the primary resistance mechanism to this antimicrobial class is caused by mutations in the genes encoding these DNA topoisomerases producing amino acid changes. Mutations are generally localized to the amino-terminal domains of GyrA and ParC, termed the *quinolone resistance-determining region* (QRDR). These mutations occur equally in the *gyrA* and *gyrB* subunits, but isolates from clinical settings usually demonstrate an exclusive prevalence for mutations in *gyrA*.

In *E. coli*, alterations in *gyrA* resulting in amino acid substitutions occur predominantly in the QRDR between positions 67 and 106. Although the presence of a single mutation in the QRDR of *gyrA* usually results in high-level resistance to nalidixic acid, the presence of additional mutations in *gyrA* and/or in another target such as *parC* is required to produce high levels of resistance to fluoroquinolones. Conversely, in gram-positive bacteria, first-step mutations leading to fluoroquinolone resistance occur in *parC* or *parE* subunits of topoisomerase IV, and second-step mutations occur in *gyrA*. Interestingly, first-step mutations in *gyrA* do not cause elevated MICs in *S. aureus*, suggesting that the primary target of the quinolone is topoisomerase IV.

β -Lactam antibiotics kill *S. pneumoniae* by targeting endogenous high-molecular-weight PBPs PBP1a, PBP1b, PBP2a, PBP2b, and PBP2x. Mutations in these PBPs lead to alteration of PBPs, which result in reduced affinity for β -lactam antibiotics. The levels of resistance are dependent on the number of mutations and PBPs involved. Mutations in PBP2 or PBP2x mediated by amino acid changes near the active site region of the PBP result in low-level resistance. Mutations in any of these transpeptidases-transglycosylases result in elevated MICs, and high-level resistance is the result of mutation in all five PBPs. Resistance to the oxazolidinones and streptogramin agents is also mediated by changes in the target site, leading to reduced affinity of the antimicrobial for its target.

Ribosomal mutation

Vancomycin-resistant *E. faecalis* mutants contain amino acid changes in domain V of the peptidyltransferase center of 23S rRNA. The most frequently encountered change is a transversion from guanine to uracil at position 2576, a mutation previously described in *E. faecium* isolated from patients who developed oxazolidinone resistance while receiving therapy. Resistance to the streptogramin antibiotic quinupristin-dalfopristin in *S. aureus* clinical isolates has been linked to alterations in ribosomal proteins with reduced affinity for streptogramin. The presence of the mutant proteins reduces the affinity of quinupristin for its target but does not affect the activity of dalfopristin; therefore the MIC susceptibility of pathogens containing this mutation increases, and there is a corresponding loss in the combined action of both antibiotics.

Enzymatic target site alteration

Enzymatic alterations of antimicrobial agent targets result in reduced affinity of the agents for their microbial targets and are exemplified by erythromycin ribosomal methylase (ERM) and by reprogramming of the peptidoglycan termini. Macrolides such as erythromycin bind the 50S subunit of the ribosome at the peptidyltransferase cavity in the proximity of the A and P loops and near adenine 2058 of 23S rRNA. Monomethylation or dimethylation of the amino group in the adenine residue of 23S rRNA results in reduced affinity of the macrolide for its target site and in elevated MICs.

Resistance to macrolides is mediated by an *ERM* gene found on plasmids and Tns that allow broad dissemination to many bacterial species. Currently, more than 20 classes of *erm* genes have been identified. Methylation of the 23S rRNA also results in cross-resistance to the lincosamide family and streptogramin B class of antibiotics. Cross-resistance to all three antibiotic groups is known as the *macrolide-lincosamide-streptogramin B (MLS) resistance phenotype*. Although MLS antibiotics are chemically distinct, they have a similar mode of action. Presumably, methylation leads to a conformational change in the ribosome that results in decreased affinity for all MLS antibiotics because the binding sites for these drugs overlap. Expression of the MLS resistance phenotype can be constitutive or inducible. However, the type of expression is not related to the classes of the *erm* gene; rather it depends on a regulatory region upstream of the methylase structure gene.

The glycopeptide vancomycin is used to treat enterococcal infections, in particular endocarditis, and is the drug of choice for the treatment of MRSA. Despite early attempts to avoid the overuse and subsequent emergence of resistance to vancomycin, widespread use resulted in the emergence of VRE isolates in health care settings. Currently, there are two choices approved for the treatment of VRE: quinupristin-dalfopristin (brand name Synercid) and linezolid (brand name Zyvox). Several agents have been approved for vancomycin-susceptible *Enterococcus* infections (e.g., daptomycin, tigecycline).

Proteins encoded by the *vanA* and *vanB* genes confer resistance to vancomycin, which is associated with alteration of the vancomycin-binding site in the cell wall and is clinically important in enterococci. *Enterococcus* spp. containing the VanA phenotype are highly resistant to vancomycin (MICs $\geq 64 \mu\text{g/mL}$) and teicoplanin (MICs $\geq 16 \mu\text{g/mL}$). The *vanA* gene resides on plasmids and on Tns that mediate spread of

the determinant. Conversely, the *vanB* determinant appears to be on large chromosomal elements. The VanB phenotype exhibits a range of susceptibilities and resistance to vancomycin but remains susceptible to teicoplanin. The VanA phenotype can be induced by vancomycin and teicoplanin, which is controlled by *vanS* and *vanR* genes, a regulatory pair that combine sensor and response regulators responsible for the control and expression of inducible vancomycin resistance.

The transmissibility of *vanA* is of great concern in the medical community, particularly transmission to MRSA, because vancomycin is the treatment of choice for MRSA. The emergence and genetic analysis of a high-level vancomycin-resistant *S. aureus* isolate (MIC = 1024 µg/mL) of clinical origin revealed the presence of a conjugative plasmid harboring Tn 1546 (*vanA*) that induces multiresistance. Potential spread of this strain in health care settings would have grave consequences for the continued therapeutic usefulness of vancomycin.

Acquisition of new targets

Microorganisms also become resistant by acquiring cellular targets with reduced affinity for the antimicrobial agent. MRSA emerged soon after the introduction of methicillin into clinical medicine in the 1960s and exemplifies the acquisition of a new target by a pathogen to respond to exposure to the toxic effects of the agent. *S. aureus* evaded the antimicrobial activity of methicillin by acquiring a mobile element carrying a staphylococcal cassette chromosome *mec*, which confers resistance to methicillin. The mobile DNA element encodes a triad of genes, *mecR1-mecI-mecA*. The *mecA* gene is responsible for methicillin resistance and encodes a new PBP, PBP2a (also PBP2a'), a bifunctional transglycosylase-transpeptidase with reduced affinity for β -lactam antibiotics, including penicillins, cephalosporins, carbapenems, and penems. The origin of the *mecA* gene remains unknown, as does the molecular basis of its nonsusceptibility to β -lactams.

Target site substitution operates in resistance to folate pathway inhibitors. Sulfonamides competitively compete for the dihydropteroate synthetase enzyme active site and block the formation of nucleotide precursors. Resistance in gram-negative and gram-positive bacteria is usually caused by the acquisition of a new enzyme that is unaffected by sulfonamides. The *sulI* and *sulII* genes, which encode drug-resistant dihydropteroate synthetases, have been found in many gram-negative bacteria. The *sulI* gene is almost always linked to other resistance genes and is located in conserved regions of integrons in Tn21-like elements carried by large, conjugated plasmids. The *sulII* gene is frequently linked genetically to a streptomycin-resistance gene on broad-host-range plasmids and on small nonconjugative plasmids.

Enzymatic inactivation of antimicrobial agents

The acquisition of enzymes that inactivate antimicrobial agents directly is one of the first mechanisms of resistance identified in bacteria and is a successful strategy used by many microorganisms to survive the action of several drug classes. Examples are enzymes that mediate hydrolysis of the β -lactam ring of β -lactam antibiotics and modification of structural moieties of aminoglycoside antibiotics. The activity of the β -lactamases was discussed previously as an intrinsic mechanism of resistance.

As mentioned earlier, β -lactamases are classified into four major classes: the serine enzymes A, C, and D and the metalloenzymes B. Class A and C β -lactamases are regarded as the most clinically significant. Class A enzyme genes are primarily found on plasmids and are constitutively expressed, whereas class C enzyme genes are primarily found on chromosomes and are inducible upon exposure to β -lactams.

The most important clinical class A β -lactamases are the families TEM, SHV, CTX, PSE, and KPC. They are usually found in gram-negative bacteria. TEM-1 is typically found in *E. coli*, *K. pneumoniae*, *K. aerogenes*, and *Haemophilus influenzae* and is generally located on transmissible plasmids. SHV-1 is usually found in clinical isolates of *K. pneumoniae* and appears to be the most common of the chromosomal β -lactamases found in this species.

With the emergence of plasmid-mediated β -lactamase resistance, concern regarding the possible widespread transmission of these resistance mechanisms led to the development of new oxyimino- β -lactam antibiotics resistant to the hydrolysis of class A β -lactamases. Although these parenterally administered cephalosporins and monobactams are excellent therapies, their continued use provided selection pressure for variants of existing β -lactamases that could hydrolyze these new antibiotics. These extended-spectrum β -lactamases (ESBLs) are known to be derivatives of the common TEM, SHV, and OXA type B β -lactamases that differ by one or more amino acid substitutions near the reactive site of the enzyme. The modified amino acid sequence yields a protein capable of extending substrate use and increasing affinity for the antibiotic target molecule. Interestingly, the enhanced spectrum of the ESBLs also makes them better substrates for BLIs. ESBLs can also hydrolyze specific sets of penicillins, cephalosporins, and monobactams, although not all ESBLs can hydrolyze all cephalosporins equally well.

CTX-M enzymes emerge from plasmid-mediated ESBLs following their mobilization from the chromosome of *Kluyvera* spp. They also belong to the class A β -lactamases and have greater activity against cefotaxime and ceftriaxone, but generally not against ceftazidime, which has important implications for laboratory detection. CTX-M enzymes show only approximately 40% identity with TEM and SHV, two commonly isolated β -lactamases. More than 125 CTX-M variants are currently known and are further divided into five subfamilies based on their amino acid homology—CTX-M-1, CTX-M-2, CTX-M-8, CTX-M-9, and CTX-M-25. CTX-Ms have mainly been found in strains of Enterobacterales. The successful spread of CTX-M genes may be influenced by several factors, including the clonal spread of strains carrying the resistance genes, the mobile genetic element responsible for its capture, and the plasmids on which it is found. CTX-M enzymes are the predominant ESBL type in parts of South America and are widespread in Europe, with CTX-M-14, CTX-M-3, and CTX-M-2 being the most common. CTX-M-15 is currently the most widespread type in *E. coli* worldwide, including in the United States.

Metallo- β -lactam resistance is increasingly being reported and is of global health interest because many metallo- β -lactams are capable of crossing species; they are the most encountered transferable carbapenemases. The most common types of metallo- β -lactams found in Enterobacterales are the VIM and IMP types and, more recently, the newest subgroup of metallo- β -lactams, named *New Delhi metallo- β -lactamase-1*

(NDM-1). The enzyme NDM-1 was first discovered in 2008 in a Swedish patient who had traveled to New Delhi and acquired a urinary tract infection caused by a carbapenem-resistant *K. pneumoniae* strain that was resistant to all antimicrobials tested, except colistin. It is now widespread and reported from many countries in Europe, Asia, Africa, Australia, and North America. Molecular examination of the first NDM-1 gene revealed that NDM-1 hydrolyzes penicillins, cephalosporins, and carbapenems, but not the monobactam, aztreonam.

Another β -lactamase reported with increasing frequency worldwide is “oxacillinase-48” (OxA-48), which belongs to class D of the Ambler classification. This enzyme was named *oxacillinase* because it was first recognized to inactivate oxacillin and methicillin. It is now known to also inhibit the cephalosporins, extended-spectrum cephalosporins, and carbapenems. This can render agents that are often the last defense against MDR bacteria ineffective.

Cephalomycins (CMYs), AmpC-like β -lactamases that hydrolyze cephalosporins and cephamycins such as cefoxitin and ceftriaxone, have recently been detected in Enterobacteriales. CMYs have been reported in *K. pneumoniae*, *E. coli*, *Proteus mirabilis*, *Salmonella*, and *K. aerogenes* from many countries, including the United States. *Salmonella* resistance to ceftriaxone is a significant public health concern because ceftriaxone is a drug of choice to treat *Salmonella* infection in humans, particularly young children. CMY is a class C β -lactamase encoded by *bla*CMY genes. To date, more than 90 *bla*CMY variants have been described, and they can reside on plasmids or chromosomes. Many studies have shown that *bla*CMY genes are transferable by conjugation and transformation.

In addition to degradation, enzyme-mediated resistance mechanisms can exert their effects by modification of the drug. As noted, amino and hydroxy radicals of aminoglycoside antibiotics form hydrogen bonds with the 30S ribosomal subunit, thus preventing mRNA translation. Resistance to aminoglycosides is mediated by efflux, changes in target site, impermeability, or enzymatic modification of the amino and hydroxy moieties appended to the cyclitol rings. The most clinically relevant is enzymatic modification of the drug.

There are three classes of aminoglycoside-modifying enzymes: aminoglycoside *N*-acetyltransferase (AAC), aminoglycoside *O*-adenyltransferase (ANT), and aminoglycoside *O*-phosphotransferase (APH). Inactivation of the aminoglycoside by the aminoglycoside-modifying enzymes is a result of the transfer of a functional group to the aminoglycoside; AAC transfers the acetyl group from acetyl-CoA to the NH_2 group, ANT transfers the nucleotide triphosphate, and APH transfers the phosphoryl group from ATP to the OH or NH_2 group. In general, only phosphorylating enzymes confer very high levels of resistance. These resistance genes are typically found on plasmids in gram-negative bacteria including the Enterobacteriales, *P. aeruginosa*, and *Acinetobacter* spp.

Another example of enzymatic alteration of a synthetic antimicrobial involves a plasmid-borne variant of an aminoglycoside acetyltransferase, AAC (6')-Ib, which acetylates fluoroquinolones and reduces their activity. Because fluoroquinolones are completely synthetic, naturally evolving antimicrobial resistance genes have not been considered a threat in the reduction of their activity. This variant enzyme acts

against some fluoroquinolones and affects resistance to aminoglycosides, implying that plasmids bearing this gene may coselect for multiple resistance.

β -Lactamase inhibitors

To enhance the therapeutic range of β -lactam antibiotics that are inactivated by β -lactamases, chemicals called BLIs were developed. They act by preventing the degradation of β -lactam antibiotics, thus extending the range of bacteria the β -lactam antibiotics are active against. Use of BLIs is important in treating infections caused by gram-negative bacteria, as β -lactamase production is an important contributor to β -lactam resistance in these pathogens. Whereas the gram-positive pathogen *S. aureus* produces β -lactamases, the resistance of this species to antibiotics is caused mostly by variant PBP_s.

BLIs have little antimicrobial activity of their own; thus they are used in combination with specific antibiotics. The majority of the currently used BLIs have a core structure resembling a β -lactam antibiotic. However, recently two BLIs whose core structure is not like a β -lactam antibiotic (non- β -lactam BLIs) have been developed: **avibactam** and **relebactam**. Currently available BLIs are effective against Ambler class A β -lactamases (tazobactam, clavulanate, and sulbactam), C β -lactamases, and D β -lactamases (avibactam). Because they have a similar chemical structure, the BLIs are processed in a way like a β -lactam antibiotic to form an initial covalent intermediate. Unlike the case with the β -lactam antibiotic, however, the formed covalent bond intermediate is very stable. This persistence between the BLI and the β -lactamase binding site deactivates the β -lactamase, preventing it from inactivating other β -lactam molecules. The antibiotics and BLIs are coformulated (Table 12.4) with similar half-lives; this is done for dosing convenience and to minimize the development of resistance.

Ambler class B β -lactamases cleave β -lactams by a mechanism like that of metalloproteases. As no covalent intermediate is formed, the mechanism of action of available BLIs is not applicable. Thus the spread of bacterial species expressing metallo- β -lactamases, such as the New Delhi metallo- β -lactamase, has caused considerable concern.

Table 12.4 β -Lactamase inhibitors

β -Lactamase inhibitors with β -lactam core	Coformulated antibiotic
Clavulanic acid or clavulanate	Amoxicillin (Augmentin), ticarcillin (Timentin)
Sulbactam	Ampicillin (Unasyn), cefoperazone (Sulperazon)
Tazobactam	Piperacillin (Zosyn and Tazocin), ceftolozane (Zerbaxa)
β -Lactamase inhibitors with non- β -lactam core	
Avibactam	Ceftazidime (Avycaz)
Relebactam	Imipenem-cilastatin (Recarbrio)
Vaborbactam	Meropenem (Vabomere)

Dissemination of resistance determinants

Case check 12.3

Mobile elements such as plasmids, Tns, and integrons are not essential for bacterial proliferation and survival. However, they can carry genes that impart selective advantages to the host bacterium, such as antimicrobial resistance genes that allow microorganisms to survive exposure to antimicrobial agents. Such mobile elements can move from one part of a genome to another or between genomes via lateral gene transfer (LGT). LGT is an important strategy for bacteria to spread antimicrobial resistance. Thus resistance genes in any organism at any location in the microbial biosphere can be mobilized and spread globally. The bacterium causing the infection in the Case in Point had the opportunity to acquire drug-resistant genes via mobile elements found in the environment.

Resistance is an evolutionary strategy that allows microorganisms to survive chemically hostile environments, such as those posed by exposure to antimicrobial agents. However, the evolution and vertical transfer of these resistance determinants to progeny is only part of the survival strategy used by microorganisms. Bacteria have the remarkable ability to share genetic resources, including resistance genes via LGT. LGT is the most important mechanism for bacteria to spread antimicrobial resistance, and it occurs on a global scale. Thus resistance genes in any organism anywhere in the microbial biosphere can be mobilized and spread globally. LGT requires at least two independent processes: (1) physical movement of DNA and (2) incorporation of DNA into the receiving genome. The mechanisms of transfer of resistance determinants from one bacterium to other bacteria are **conjugation**, **transformation**, and **transduction** (see [Chapter 1](#)). The mobile elements that carry the resistance genes transferred through LGT are plasmids, Tns, and integrons.

Plasmids are circular DNA elements that replicate independently of the chromosome and can acquire and exchange information with the chromosome and other host-resident plasmids. Plasmids can be conjugative and self-transmissible or nonconjugative, requiring mobilization by conjugative plasmids. Plasmid-encoded traits are typically not essential for bacteria to survive but carry genes that impart some selective advantage to the host bacterium, such as virulence determinants, adhesions, and antimicrobial drug resistance. Plasmids that carry resistance genes are called *R plasmids* or *R factors* and play a key role in spreading antimicrobial resistance genes. Since their discovery in the 1950s, antimicrobial resistance plasmids have been increasingly associated with gram-positive and gram-negative bacterial pathogens and with commensal organisms.

Plasmid-associated resistance genes have been characterized for most clinically available antimicrobials. It is not uncommon for a single plasmid to mediate resistance to multiple antimicrobials and be shared among different bacterial genera simultaneously. For example, the IncA/C MDR plasmid carries resistance to many different classes of antimicrobials, including β -lactams, aminoglycosides and aminocyclitols,

tetracyclines, phenicols, quaternary ammonium compounds, sulfonamides, and trimethoprim. This plasmid has been broadly disseminated among MDR zoonotic pathogens, such as *Yersinia pestis*, *Yersinia ruckeri*, *E. coli*, and various serovars of *Salmonella*.

Until recently, quinolone resistance was believed to arise solely from chromosomal mutations in genes encoding target enzymes or via active efflux. It is now clear that plasmid-mediated quinolone resistance occurs and is conferred by unusual resistance determinants, including *qnr*, *aac(6')-Ib-cr*, and *qepA* (an efflux pump belonging to the major facilitator subfamily). The *qnr* determinant was discovered in 1998 in a *K. pneumoniae* isolate from Birmingham, Alabama, and was found in an integron-like structure on the MDR plasmid pMG252. The plasmid encoded Qnr proteins derived from *E. coli*, *Klebsiella oxytoca*, and *K. pneumoniae* isolates recovered from different geographic sources (China, Europe, and the United States) show almost identical amino acid residues, indicating that these proteins likely have a common origin. It appears that the *qnr* genes were acquired from chromosomal genes in aquatic bacteria and now are usually associated with mobilizing or transposable elements on plasmids. There is also evidence supporting a role for these plasmids in linking resistance to quinolones and ESBLs. This is especially troubling, given the importance of fluoroquinolones and β -lactams in clinical medicine.

Even more troubling in relation to plasmid-encoded antimicrobial resistance is the emergence of the plasmid-mediated, mobilized colistin resistance gene (*mcr-1*) in Enterobacterales. The *mcr-1* gene confers resistance to many of the last-resort antimicrobials, including colistin. This is extremely concerning from a public health perspective because *mcr-1* is transferred via horizontal gene transfer in Enterobacterales. The *mcr-1* gene is distributed on at least five continents, and isolates with the *mcr-1* gene have been recovered from human infections, including in the United States.

Tns are DNA elements that encode transposition and excision functions and can move from one place on the chromosome and/or plasmid to another. Transposase, an enzyme that facilitates nonhomologous recombination, mediates the transposition event. Much like plasmids, Tns are also capable of carrying antimicrobial resistance genes and shuttle these determinants among plasmids and the chromosome. Tns can be very simple, composed of the **insertion sequence (IS)** elements, or much more complicated, as in composite Tns. ISs are short DNA sequences that act as a simple transposable element. ISs have two major characteristics: (1) they are small relative to other transposable elements, and (2) they code only for proteins used in the transposition activity. These proteins usually include transposase, which catalyzes the enzymatic reaction allowing the IS to move, and also one regulatory protein, which stimulates or inhibits the transposition activity.

ISs can form composite transposable genetic elements, such as Tn10, with the IS elements forming the proximal and distal ends and genetic material that codes for antimicrobial resistance located in between. ISs associated with antimicrobial resistance include IS256, which was linked to amikacin, gentamicin, and oxacillin resistance in *Staphylococcus pseudintermedius*. Several resistance determinants in many different bacterial species are transmitted via composite Tns. Transmission of a Tn from one bacterial species to another can

be accomplished by insertion into a conjugative plasmid or via a conjugative Tn. Conjugative Tns appear to be a hybrid between Tns and plasmids and have been identified in many gram-negative and gram-positive bacteria.

Plasmid NR1 isolated from *Shigella flexneri* is the archetype plasmid responsible for the dissemination of antimicrobial resistance utilizing these elements. NR1 is a 94.5-kb multiple antimicrobial resistance plasmid that carries the genes for self-transmissibility and autonomous replication. NR1 also carries a resistance-determining region bound by direct repeats and is self-transmissible as Tn2670. Nested within Tn2670 is Tn21, a transposon of particular interest not only because it exhibits the transpositional characteristic of Tns and the presence of resistance determinants, but also because it contains a potentially mobile DNA element, the integron.

Integrans are genetic elements that capture mobile gene cassettes by site-specific recombination. Integrans share a common recombination system composed of a gene (*intI*) that encodes a site-specific recombinase (IntI) and an adjacent primary recombination site (*attI*) into which gene cassettes can be integrated. The integron also contains a promoter that directs transcription of any cassette inserted into the 5' conserved sequence of the integron. The *attI* is a 59-base element recognized by IntI that mediates insertion into the integron. Multiple gene cassettes can be arranged in tandem, and more than 60 distinct cassettes have been identified. Cassette-associated genes have been shown to confer resistance to β -lactams, aminoglycosides, phenicols, trimethoprim, streptothricin, and quaternary ammonium compounds.

So far, five classes of integrans have been described based on the *intI-attI* combinations. Among enteric bacteria and several different genera, class I integrans are the most frequently identified. Integrans are usually identified in conjunction with streptomycin and trimethoprim-SMZ-resistant bacteria isolated from food animals and human infections. The inclination to exchange genes increases concern about the possible spread of drug resistance determinants from commensal or nonclinical organisms in animals and humans to human pathogens. Integrans can be chromosomally encoded and are not independently mobile; however, they are usually mobilized on plasmids and Tns. Clonal expansion of drug-resistant bacteria together with the movement of antimicrobial resistance gene cassettes within and between integrans play important roles in the spread of MDR bacteria.

As noted previously, vancomycin is an important antibiotic used to treat infections caused by MRSA. However, a MRSA isolate of clinical origin was found to contain a conjugative MDR plasmid that encoded resistance to vancomycin, trimethoprim, β -lactams, aminoglycosides, and hospital disinfectants. Genetic analysis revealed the presence of a multiresistant conjugative plasmid harboring Tn1546 (VanA). A Tn1546-like transposable genetic element encoding for transposition, regulation of VanA expression, and resistance is also found in enterococci. The data suggest that the interspecies transfer of Tn1546 occurs from a coresident isolate of *E. faecalis* to MRSA. Resistance to vancomycin can be spread by the transposition of 1547 to a conjugative plasmid and transferred by conjugation to recipient strains or by excision and circularization of the Tns, followed by conjugation.

In addition to self-transmissible mobile DNA elements, antimicrobial resistance determinants can be spread among

bacteria via uptake of naked DNA from the surrounding environment (transformation) or by infection with a bacteriophage carrying resistance genes (transduction). Transformation was the first mechanism of DNA transfer to be discovered among prokaryotes and involves DNA scavenging by a bacterium after the death and deterioration of a nearby bacterium. The DNA in a dead bacterium degrades and is broken into fragments that are released into the surrounding milieu, which can then be internalized by transformation-competent recipients. If antimicrobial resistance genes are included in the degraded DNA, they can be expressed when the DNA is taken up by a nearby bacterium and incorporated into the bacterial genome.

Genetic exchange via transduction involves bacteriophage infection of a bacterium, phage replication, packaging of some of the bacterial DNA with the phage DNA (which may include resistance determinants) in the phage capsid, with lysis of that bacterium, and bacteriophage infection of subsequent bacteria. On subsequent infection, those resistance determinants can be transferred to the newly infected bacterium. The contribution of transformation and transduction in the evolution of MDR is difficult to assess, but laboratory demonstrations indicate that it might play a role in antimicrobial resistance development.

Nanotechnology to deliver therapeutic agents

Nanoparticles are less than 100 nm in size and have unique biological, physical, and chemical properties at these dimensions. The nanomaterial can be loaded with drugs, biomolecular diagnostic tools, and contrast agents that can help locate the agents and understand their action in real time. These tools can help us understand the mechanisms of drug resistance more accurately. Furthermore, based on this information, new formulations can be developed to overcome MDR. In many cases, the unique properties of nanomaterial facilitate the fast diffusion of the drug to the infection, which can significantly enhance treatment.

Nanomedicine is being tested to deliver various therapeutic drugs to tissue. This technology has the potential to treat infectious diseases and cancer. For example, mRNA vaccines for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) utilize lipid nanoparticles to deliver the mRNA encoding for the SARS-CoV-2 spike protein into the cell and have demonstrated high efficacy after two doses. Nanoencapsulation delivery systems are used to increase the circulation time of drugs, which allows the drugs to reach their destination in the body without degradation. Nanoencapsulation can increase the solubility and improve the pharmacokinetic profiles of insoluble drugs, and in many cases, targeted drug delivery greatly enhances the bioavailability to the target tissues. Encapsulating the drug allows more surface modification, and encapsulated ingredients can be stabilized for longer periods.

Several nanoparticle-based drug delivery systems are approved for clinical use to treat a variety of infectious diseases. Bacterial infections are known to trigger inflammatory reactions that can stimulate vascular permeability. Increased permeability and dysfunctional lymphatic drainage have

been shown to facilitate the accumulation of drug-loaded nanoparticles at the infection site. Under physiologic conditions, pathogenic bacteria have a negative surface charge. Cationic nanoparticles are capable of binding to bacteria by electrostatic interactions. Nanoparticles also have been coated with ligands that bind specifically to bacterial receptors. To reach intracellular bacteria, nanoparticles have been coated with ligands binding to macrophage receptors. The macrophage takes up the nanoparticle, delivering the loaded drug.

As mentioned previously, combination therapy with synergistic drugs is becoming more commonly used to combat MDR bacteria. A difficulty with this strategy is the differing pharmacokinetics, biodistribution, and membrane-penetrating properties of different drugs. Loading multiple drugs in nanoparticles can overcome these difficulties. For example, isoniazid and rifampin have been loaded into liposomes. This therapeutic strategy has been shown to be more effective in treating tuberculosis compared with free drugs at the same dosage.

Nanoparticle delivery systems include liposomes, polymeric nanoparticles, and dendrimers. Liposomes are closed, continuous bilayered structures of synthesized polymers that can be used for nanoencapsulation. They are stable and perfect for storing and stabilizing the drug delivery system. In the liposome artificial membrane, small, closed vesicles can be formed that make up a lipid bilayer. This lipid bilayer encloses a small droplet of water, approximately 10 to 20 nm. These small structures can be used to deliver the drug.

Nanoshells are about 5 to 10 times smaller than liposomes, with a pore size of around 2 nm. Nanoshells consist of vesicular porous structures that allow them to be effective in targeting the drug. They are synthesized from silica or calcium phosphate. Nanoshells are biodegradable and trap the drugs in the interior space, actively targeting the drug site. They release drugs from their internal cavities as the structure erodes. The toxicity levels for nanoshells are lower than for other delivery systems but are subject to further investigation.

Another way of delivering drugs is by using cochleates. These are small, stable lipid structures composed of a bilayer sheet that is rolled up into a spiral-like structure. The benefits of this structure are that cochleates have higher stability, and they can deliver drugs to negatively and positively charged species. They are used typically in oral delivery, as opposed to other methods.

POINTS TO REMEMBER

- Resistance to antimicrobial agents may be genetically intrinsic or acquired; both types can be found in the same pathogen.
- β -Lactam antibiotics, which work by inhibiting cell wall synthesis, contain a four-member ring and include the penicillins, cephalosporins, monobactams, and carbapenems.
- Quinolones interfere with DNA replication by targeting DNA gyrases and topoisomerases.
- Protein inhibitors include aminoglycosides, tetracyclines, macrolides, streptogramins, chloramphenicol, and linezolid.
- BLIs are used with β -lactam antibiotics to increase the activity of the antibiotic.

- Impermeability and efflux mechanism of resistance can produce multidrug-resistant phenotypes.
- Conjugation, transformation, and transduction are the mechanisms of transfer of resistance determinants among bacteria.
- The mobile elements that carry resistance genes during lateral gene transfer are plasmids, Tns, and integrons.
- A single organism can acquire multiple mechanisms of resistance, including different mechanisms of conferring resistance to the same compound.
- Antimicrobial mechanisms of resistance and their dissemination are not static processes.
- Nanoparticles are being used to deliver various drugs, including antimicrobial agents and vaccines, into tissue.

LEARNING ASSESSMENT QUESTIONS

1. Antibiotics can be:
 - a. Natural molecules.
 - b. Synthetic molecules.
 - c. Semi-synthetic molecules.
 - d. All of the above.
2. Which of the following antimicrobials act on cell wall biosynthesis?
 - a. Macrolides and phenicols
 - b. Tetracycline and streptomycin
 - c. β -Lactams and glycopeptides
 - d. Fluoroquinolone and sulfamethoxazole
3. Which of the following antimicrobials are new analogues of older classes?
 - a. Glycylcycline from tetracyclines
 - b. Fluoroquinolone from glycopeptides
 - c. Ketolides from macrolides
 - d. Both a and c
4. The most used inhibitors of cell wall biosynthesis act on:
 - a. Synthesis of precursors in the cytoplasm.
 - b. Transpeptidation linking and maturation.
 - c. Insertion of glycan units into the cell wall.
 - d. Both b and c
5. Which of the following antimicrobial classes does not include semi-synthetic and natural derivatives?
 - a. Aminoglycosides
 - b. Fluoroquinolones
 - c. Glycopeptides
 - d. β -Lactams
6. Intrinsic drug resistance is:
 - a. Often caused by genetic change.
 - b. Found in only a few members (strains) within a species.
 - c. Transmitted vertically.
 - d. Typically found on mobile elements.
7. Which mechanisms of antimicrobial resistance are intrinsic and acquired?
 - a. Efflux
 - b. Biofilm
 - c. Acquisition of new targets
 - d. Gram-negative outer membrane
8. Plasmids can contain which of the following?
 - a. Transposons
 - b. Insertion sequences
 - c. Integron cassettes
 - d. All of the above

9. Transposons do not contain which of the following?
 - a. Transposase gene
 - b. Cytoplasmic membranes
 - c. Excision protein genes
 - d. Antibiotic resistance determinants
10. Which of the following characteristics apply to efflux pumps?
 - a. They are found in gram-positive and gram-negative bacteria.
 - b. They are transporter proteins.
 - c. They have single or multiple substrates.
 - d. All of the above.
11. Enzymatic modification of aminoglycosides is *not* caused by which of the following?
 - a. Dimethylation
 - b. *N*-acetylation
 - c. *O*-phosphorylation
 - d. *O*-adenylation
12. Which of the following is *not* a characteristic of integrons?
 - a. Potentially mobile element
 - b. Gene cassettes
 - c. Peptidoglycan
 - d. 59-bp element
13. Which of the following antimicrobials acts predominantly on cell membrane integrity?
 - a. Aminoglycosides
 - b. Polymyxins
 - c. Tetracyclines
 - d. Penicillins
14. Which of the following is a non- β -lactam β -lactamase inhibitor?
 - a. Relebactam
 - b. Ticarcillin
 - c. Clavulanate
 - d. Sulbactam
15. Serine-based β -lactamases appear to have evolved from the penicillin-binding proteins of bacteria. True or false?

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Explain the rationale behind the performance of antimicrobial susceptibility tests.
2. Describe the method for selection of specific drugs in testing and reporting.
3. Define minimal inhibitory concentration (MIC).
4. Justify the methods used for determining MICs.
5. Explain how zone-interpretive criteria used with the disk diffusion test are established.
6. List the variables that must be controlled when antimicrobial susceptibility tests are performed.
7. Justify test modifications for antimicrobial susceptibility testing of *Helicobacter/Campylobacter* spp., *Streptococcus* spp. (including *Streptococcus pneumoniae*), *Haemophilus* spp., *Neisseria gonorrhoeae*, *Neisseria meningitidis*, and obligate anaerobes.
8. Explain the principles behind automated antimicrobial susceptibility test methods.
9. Discuss several commercially available antimicrobial susceptibility test systems in current use.
10. Justify testing bacterial isolates for β -lactamase.
11. List the organisms for which β -lactamase testing is indicated.
12. Explain the reliable methods for detection of methicillin-resistant *Staphylococcus aureus*, vancomycin-intermediate *S. aureus*, and vancomycin-resistant *S. aureus*.
13. Discuss use of the D-zone test.
14. Describe the significance of high-level aminoglycoside resistance in enterococci.
15. Describe extended-spectrum β -lactamases and carbapenemases and assays to detect them.
16. Justify testing for extended-spectrum β -lactamases and carbapenemases.
17. Discuss quality control procedures for antimicrobial susceptibility tests.
18. Describe how antibiograms can be used to help verify the accuracy of results generated by testing patient isolates.
19. Discuss situations in which cumulative antibiograms may help guide antimicrobial therapy.

20. Explain how to select a particular susceptibility test method for routine use.
21. Explain the antimicrobial susceptibility test interpretive results of *nonsusceptible*, *susceptible*, *intermediate*, and *resistant*.
22. Explain the function of the International Organization for Standardization.
23. Describe the minimum bactericidal concentration (MBC) test and the indications for performing this test.
24. Justify determining the MBC of bacterial isolates.
25. Define *synergism*, *antagonism*, and *indifference* as related to testing combinations of antimicrobial agents.
26. Describe the serum bactericidal test and the indications for performing this test.
27. Explain how molecular probes might be used to detect antimicrobial resistance.
28. Discuss methods used for measuring concentrations of antimicrobial agents in serum and body fluids and when such tests are used.

KEY TERMS

Antagonism	Minimal inhibitory concentration (MIC)
Antibiogram	Minimum bactericidal concentration (MBC)
β -Lactamases	Nonsusceptible
Borderline oxacillin-resistant isolates	Oxacillin-salt screen plate
Breakpoint	Penicillinase-producing <i>Neisseria gonorrhoeae</i> (PPNG)
Carbapenemase-producing Enterobacterales (CPE)	Penicillinase-resistant penicillins
Chromosomally mediated resistant <i>Neisseria gonorrhoeae</i> (CMRNG)	Persister cells
Clinical and Laboratory Standards Institute (CLSI)	Resistant
Cumulative antibiogram	Selective reporting
D-zone test	Serum bactericidal test (SBT)
Etest	Susceptible
Extended-spectrum β -lactamase (ESBL)	Synergism
Heteroresistant	Time-kill assay
High-level aminoglycoside resistance	Tolerance
Indifference	Trailing
Intermediate	U.S. Food and Drug Administration (FDA)
Kirby-Bauer test	Vancomycin agar screen plate
McFarland turbidity standards	Vancomycin-intermediate <i>Staphylococcus aureus</i> (VISA)
<i>mecA</i> gene	Vancomycin-resistant enterococci (VRE)
Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA)	Vancomycin-resistant <i>Staphylococcus aureus</i> (VRSA)
	Zone of inhibition

Case in point

The microbiology laboratory supervisor was reviewing patient reports that the floating laboratory scientist had generated earlier in the day. She saw a susceptibility report for *Staphylococcus aureus* isolated from a patient's wound that included the following disk diffusion testing results: cefazolin-S, ceftiofur-R, clindamycin-R, erythromycin-R, penicillin-R, and vancomycin-S. However, there was no result for oxacillin. The supervisor realized that the laboratory

scientist who had reported these results might have forgotten the current method for detecting **methicillin-resistant *Staphylococcus aureus* (MRSA)** and reporting rules for β -lactam agents and MRSA. She reminded the laboratory scientist of the special testing method and reporting rules, and the laboratory scientist corrected and rereleased the report, which was as follows: clindamycin-R, erythromycin-R, oxacillin-R, penicillin-R, and vancomycin-S.

Issues to consider

After reading the patient's case history, consider:

- Use of surrogate antimicrobial agents to test for resistance or susceptibility for the drug reported
- Editing certain susceptible results to resistant, and not reporting related drugs, when bacteria with specific types of resistance are encountered
- Modifications of standard tests that might be necessary to detect specific types of emerging resistance

Procedures in antimicrobial susceptibility testing

Antimicrobial susceptibility testing is performed on bacteria and fungi isolated from clinical specimens to determine which antimicrobial agents might be effective in treating infections caused by these organisms. Only organisms that are likely to be contributing to an infection should be tested. Testing of organisms that are not involved in an infection is misleading to the physician and could lead to unnecessary treatment and a more serious infection with development of antimicrobial resistance.

A major goal of the clinical microbiology laboratory is to identify organisms that are causing infections. Often, these organisms must be distinguished from the normal microbiota that can reside at the site of the infection, although in some situations the microbiota that resides at the site of the infection may be contributing to the infection. Therefore it must be determined which organisms from a specimen are clinically relevant and will be identified and tested for susceptibility to antimicrobials. Most microbiology laboratories have guidelines for determining when and on which microorganism susceptibility testing will be done. When in doubt about the significance of an organism, it is best to discuss the situation with the attending physician and microbiology laboratory director.

In clinical laboratories, susceptibility testing on bacteria can be performed by classic disk diffusion or dilution (**minimal inhibitory concentration [MIC]**) methods. More commonly, one of several different types of commercial automated antimicrobial susceptibility test systems may be used. Protocols that describe these methods are published and frequently updated by the **Clinical and Laboratory Standards Institute (CLSI)** in the United States. The European counterpart is The European Committee on Antimicrobial Susceptibility Testing (EUCAST). Worldwide, antimicrobial susceptibility testing is guided by the International Organization for Standardization (ISO). This organization is a worldwide federation of national standards bodies. The work of preparing international standards is conducted

through ISO technical committees, whose main task is to prepare international standards. Publication as an international standard requires approval by at least 75% of the member bodies casting a vote. In all cases, it is important to maintain an awareness of which antimicrobial agents are appropriate to test, the reliability of various test systems for detecting antimicrobial resistance, and strategies for effectively communicating results on laboratory reports to those who must be informed.

Reasons and indications for performing antimicrobial susceptibility tests

Antimicrobial susceptibility testing should be performed on a bacterial isolate from a clinical specimen if the isolate is determined to be a probable cause of the patient's infection and the susceptibility of the isolate to antimicrobials cannot be reliably predicted based on previous experience with the bacteria at a specific health care facility. Although information can be determined on the susceptibility of specific bacteria from the literature, there may be significant differences at a specific health care facility, based on the patient population. Susceptibility tests are not performed on bacteria that have a predictable susceptibility pattern to antimicrobial agents. For example, group A β -hemolytic *Streptococcus* is not routinely tested because it is universally susceptible to penicillin, the drug of choice in treating infections caused by this bacterium. In contrast, the recommended agent for treating *Staphylococcus aureus* infections is oxacillin, but not all *S. aureus* isolates are susceptible to oxacillin. Thus susceptibility testing is routinely indicated for an *S. aureus* isolate that is suspected of causing an infection.

Susceptibility testing of isolates can also provide information on decreases in the susceptibility of bacteria to antimicrobials. A separate set of critical MICs other than the MICs used to judge a bacterium susceptible or not susceptible to an antimicrobial are developed for this purpose. These values are termed *epidemiologic cutoff values* (ECVs). ECV MICs separate bacterial populations into those likely to be wild type (susceptible) versus those that are becoming resistant, either by mutation or acquisition of resistance genes. When the ECV MIC value is achieved, it is an indication that the bacterium is likely developing resistance to the antimicrobial. This information can be used to adjust the use of that antimicrobial in the health care facility to delay or avoid those species from becoming resistant to the antimicrobial. Such adjustments include discontinuing the use of the drug for a time, reserving use of the drug for specific patients, using the drug in combination with another, and generally using an antimicrobial of a different class to treat infections caused by that bacterium.

Factors to consider when determining whether susceptibility testing is warranted

In addition to the unpredictable susceptibility of a potential pathogen, other important factors must be considered when

determining whether antimicrobial susceptibility testing is warranted, including:

- Body site from which the bacterium was isolated
- Presence of other organisms and quality of the specimen from which the organism was grown
- Host's status

Body site

Susceptibility tests are not routinely performed on organisms isolated from an anatomic site for which they are normal inhabitants. For example, *Escherichia coli* is normal microbiota in the lower gastrointestinal tract and therefore would not be tested when isolated from stool. However, *E. coli* from a blood culture would be tested because blood is normally sterile. Similarly, viridans group streptococci represent normal microbiota in throat specimens and would not be routinely tested. Coagulase-negative staphylococci isolated from multiple blood cultures would be tested; but because coagulase-negative staphylococci are commonly found on skin surfaces, these bacteria would not normally be tested when isolated from superficial wound specimens. Yeasts isolated in low numbers in vaginal specimens or in the throat, if other microbiota is present, would not be considered significant. Testing of normal microbiota isolates, or isolates likely to represent contamination or colonization, should be avoided because reporting antimicrobial susceptibility results may encourage a physician to treat a nonpathogen and prevent further investigation of the true cause of the patient's problem.

Presence of other bacteria and quality of the specimen

The isolation of an organism in pure culture is less likely to represent contamination than a mixed culture. The presence of more than two species at greater than 10^5 colony-forming units (CFU) per milliliter isolated from urine suggests contamination, and these organisms may not require susceptibility testing; however, a pure culture of *E. coli* at more than 10^5 CFU/mL would likely represent true infection and would be tested. A few colonies of *Klebsiella pneumoniae* in the presence of oropharyngeal microbiota in a sputum culture may not be significant. However, in the absence of oropharyngeal microbiota, a few colonies of this species, particularly if gram-negative bacilli were noted on a direct Gram stain of the sputum, can be significant and warrant susceptibility testing.

Host status

The host status of the patient often influences susceptibility testing decisions. In an immunocompromised patient, species usually viewed as normal microbiota might be responsible for an infection and therefore may require susceptibility testing. Also, in patients who are allergic to penicillin and have a β -hemolytic streptococcal infection (e.g., group A or group B), erythromycin or clindamycin are alternative drugs of choice. Occasionally β -hemolytic streptococci are resistant to these agents, so testing might be performed.

Selecting antimicrobial agents for testing and reporting

Currently, more than 50 antimicrobial agents are in use for treating bacterial and fungal infections. Although hundreds more exist, many of these have comparable clinical efficacy. Each laboratory must determine which agents are appropriate for routine testing against various organisms in its setting. Testing and reporting protocols are formulated with input from drug prescribers, representatives from the microbiology laboratory, infectious diseases and other services, the institution's pharmacy, and the therapeutics committee regarding the clinical usefulness of various agents at an institution. Antimicrobial package inserts written by the **U.S. Food and Drug Administration (FDA)** should be consulted for information concerning the dosing and indications for which the antimicrobial was approved and the performance of the antimicrobial agent during initial clinical trials.

It is important that the antimicrobial drugs used by the laboratory match the institutional formulary as closely as possible. From the laboratory perspective, the limiting factor for the number of drugs tested is usually the number that can be practically tested with a specific method. For example, the standard disk diffusion test for bacteria uses a 150-mm agar plate, which can accommodate no more than 12 disks. In the case of MIC test panels, 12 to 15 antimicrobials can be tested on one panel. Some automated antimicrobial susceptibility systems can test more drugs at one time.

The patient population must be considered in the choice of antimicrobial agents to be tested. Some agents are contraindicated in pediatric patients (e.g., fluoroquinolones, which can impair cartilage development, and tetracycline, which damages developing teeth). Emphasis should be placed on testing oral agents when dealing with outpatient specimens. Additional guidelines for developing a testing and reporting strategy are found in the CLSI documents for disk diffusion or MIC testing. These documents include tables that list primary and secondary agents appropriate for testing against various organism groups. CLSI guidelines are updated at least annually.

Selection of test batteries

Generally, a laboratory will define a battery of 10 to 15 antimicrobial agents for routine testing against the Enterobacterales, *Pseudomonas* spp., nonfastidious gram-negative bacilli (e.g., *Acinetobacter* spp., *Stenotrophomonas maltophilia*, and *Burkholderia cepacia*), staphylococci, and enterococci. Sometimes a separate battery is performed for urine isolates, representing drugs appropriate for treating urinary tract infections (UTIs). A supplemental battery that contains antimicrobial agents with enhanced activity may be included by laboratories that encounter a significant number of bacteria resistant to the more commonly used antimicrobials.

Case check 13.1

Specific rules are developed by laboratories for dealing with specific susceptibility test results based on institutional data and data from outside sources. These include reporting antimicrobial results on appropriate bacteria (e.g., gram-positive vs. gram-negative) from relevant clinical sites.

Reporting of susceptibility test results

Because the identity of the bacterial isolate is sometimes unknown when the susceptibility test is performed, some drugs that are inappropriate to report may be tested on an isolate. In such cases, a drug should not be indiscriminately reported because results can be misleading. Some drugs may appear active against certain species in vitro but are inappropriate for clinical use (e.g., most cephalosporins against methicillin-resistant *Staphylococcus aureus* [MRSA], trimethoprim-sulfamethoxazole against enterococci). The final decision about the antimicrobials to report is made once the identity of the isolate is known (sometimes a preliminary identification is sufficient), along with the overall susceptibility results and specimen source.

Reporting protocols should be developed following discussion with infectious disease clinicians, pharmacists, and others who have clinical experience with the antimicrobial therapy practices of the institution. A primary tenet of antimicrobial therapy is to use the least toxic, most cost-effective, and most clinically effective agents and to refrain from use of costly, broader-spectrum agents. Achieving physician compliance with this objective can be difficult. If all drugs tested are reported, inappropriate antimicrobial prescribing may occur, so most laboratories refrain from reporting broad-spectrum agents if narrower-spectrum agents are active in vitro. CLSI provides guidance for development of a selective or so called *cascade* reporting protocol. In addition, antimicrobial stewardship programs in many institutions help educate and guide clinicians in appropriate and responsible antimicrobial therapy.

For several organism groups, the CLSI categorizes antimicrobial agents into four groups. An example of a listing for Enterobacterales is seen in [Box 13.1](#). As a general guideline, it is suggested that within an antimicrobial class, primary (group A) agents be reported first and secondary (group B) agents be reported only if one of the following conditions exists:

- The isolate is resistant to the primary agents.
- The patient cannot tolerate the primary agents.
- The infection has not responded to the primary agents.
- A secondary agent would be a better clinical choice for the infection (e.g., meningitis).
- Bacteria were isolated from another site, and a secondary agent might be useful for treating both infections.

For example, a primary cephalosporin, such as cefazolin (a first-generation cephalosporin), would be a reasonable choice for a susceptible *E. coli*, and secondary cephalosporins, such as cefuroxime (second-generation cephalosporin) or cefotaxime (third-generation cephalosporin), would generally not be required. An exception would occur with meningitis because third-generation cephalosporins cross the blood-brain barrier much more effectively than their first-generation counterparts. Gentamicin is usually the aminoglycoside of choice for treating serious infections caused by gentamicin-susceptible *Pseudomonas aeruginosa*, and tobramycin or amikacin may be considered for gentamicin-resistant isolates. Aminoglycosides are not effective for treating meningitis because they do not readily cross the blood-brain barrier.

A secondary agent may also be reported if the patient has a polymicrobial infection, and a secondary (but not a primary)

BOX 13.1 Suggested groupings of antimicrobial agents: Enterobacterales**Group A primary test and report**

Ampicillin^a
Cefazolin^b
Gentamicin^a
Tobramycin^a

Group B primary test report selectively

Amikacin^a
Amoxicillin–clavulanic acid
Ampicillin–sulbactam
Azithromycin^c
Ceftazidime–avibactam
Ceftolozame–tazobactam
Imipenem–relebactam
Meropenem–vaborbactam
Piperacillin–tazobactam
Cefuroxime
Cefepime
Cefotetan
Cefoxitin
Cefotaxime^{a,b} or ceftriaxone^{a,b}

Cefiderocol
Ciprofloxacin^a
Levofloxacin^a
Doripenem
Ertapenem
Imipenem
Meropenem
Trimethoprim–sulfamethoxazole^a

Group C supplemental report selectively

Aztreonam
Ceftazidime
Ceftaroline
Chloramphenicol^{a,d}
Tetracycline^e
Group U supplemental for urine only
Cefazolin
Fosfomycin^f
Nitrofurantoin
Sulfisoxazole
Trimethoprim

^aWhen fecal isolates of *Salmonella* and *Shigella* spp. are tested, only ampicillin, a fluoroquinolone, and trimethoprim–sulfamethoxazole should be tested and reported routinely. In addition, a third-generation cephalosporin should be tested and reported (also chloramphenicol and azithromycin if requested) for extraintestinal isolates of *Salmonella* spp. Routine testing of nontyphoidal intestinal *Salmonella* is not indicated, but testing on all *Shigella* isolates is indicated. For *Salmonella* and *Shigella* isolates, aminoglycosides, first- and second-generation cephalosporins, and cephamycins can appear active in vitro but should not be reported as they are ineffective clinically.

^bCefotaxime/ceftriaxone should be reported on CSF isolates instead of cefazolin.

^cReport for *S. Typhi* or *Shigella* spp. only.

^dNot routinely reported on isolates from urine.

^eOrganisms susceptible to tetracycline are considered susceptible to doxycycline and minocycline; organisms intermediate or resistant to tetracycline may be susceptible to doxycycline, minocycline, or both.

^fTest and report on urinary isolates for *E. coli* and *E. faecalis* only.

agent would more likely be effective against all pathogens present. Similarly, a secondary agent may be reported if the patient has a disseminated infection, and a secondary agent would more likely be effective at all sites. Agents with very broad-spectrum activity or increased potency (group C) may be tested and reported for the reasons listed for secondary agents. In addition, group C agents would be considered for routine testing if a particular institution encounters large numbers of isolates resistant to group A and group B agents. Finally, agents with activity only in the urinary tract should be reported only on isolates from urine; these drugs concentrate in the urine and are clinically ineffective in treating other infections.

Traditional antimicrobial susceptibility test methods

Inoculum preparation and use of McFarland standards

Inoculum preparation

Inoculum preparation is one of the most critical steps in susceptibility testing. Inocula are prepared by adding cells from four to five isolated colonies of similar colony morphology growing on a noninhibitory agar medium to a broth medium

and then allowing them to grow to log phase at 35° C for 2 to 6 hours, until they reach the McFarland 0.5 standard (see later). Four to five colonies, rather than a single colony, are selected to minimize the possibility of testing a colony that might have been derived from a susceptible mutant. Inocula can also be prepared by suspending colonies grown overnight on an agar plate directly in broth or saline. This direct inoculum suspension preparation technique is required for staphylococci and for bacteria that grow unpredictably in broth (e.g., fastidious bacteria) but can be used for any organism. Because it does not rely on growth in an inoculum broth, the use of fresh (16- to 24-hour) colonies is imperative.

McFarland turbidity standard

The inoculum concentration of bacteria to be tested must be standardized. False-susceptible results may occur if too few bacteria are tested, and false-resistant results may be the outcome of testing too many bacteria. The most widely used method of inoculum standardization involves comparing the turbidity of the inoculum preparation with **McFarland turbidity standards**. McFarland standards can be prepared by adding specific volumes of 1% sulfuric acid and 1.175% barium chloride to obtain a barium sulfate solution with a specific optical density. The most used is the McFarland 0.5 standard, which contains 99.5 mL of 1% sulfuric acid and 0.5 mL of 1.175% barium chloride. This solution is dispensed into tubes comparable with those used for inoculum preparation, which are sealed tightly and stored in the dark at room

temperature. The McFarland 0.5 standard provides turbidity comparable with that of a bacterial suspension containing approximately 1.5×10^8 CFU/mL. Suspensions of latex particles can be used as a simpler, more stable alternative to barium sulfate to achieve turbidity comparable with that of the McFarland standard.

Inoculum standardization

To standardize the inoculum, the inoculated broth or direct suspension is vortexed thoroughly. The traditional method of comparison is to position the tube side by side with the McFarland 0.5 standard against a white card containing several horizontal black lines (Fig. 13.1) under adequate lighting. The turbidities are compared by looking at the black lines through the suspension. The suspension is too dense if it is more difficult to see the lines through the inoculum suspension than through the McFarland 0.5 standard. In such a case, the inoculum would be diluted with additional sterile broth or saline. If the test suspension is too light, more organisms are added, or the suspension is reincubated (depending on the inoculum preparation protocol) until the turbidity reaches that of the McFarland standard. Once standardized, the inoculum suspensions should be used within 15 minutes of preparation.

Fig. 13.1 *Left*, The tube contains a McFarland 0.5 turbidity standard. *Right*, The tube contains a test bacterial suspension that has turbidity greater than that of the McFarland standard; it is more difficult to see the black lines through the test suspension than through the McFarland standard. Sterile saline or broth must be added to the test suspension to dilute it until the turbidity matches that of the McFarland standard.

A convenient and more precise alternative to the traditional, highly subjective visual adjustment to match the McFarland standard is the use of a nephelometer or spectrophotometer. Several simple, commercially available benchtop instruments are commonly used for more objective standardization of bacterial inocula (Fig. 13.2).

Dilution susceptibility test methods

Principle

Dilution antimicrobial susceptibility test methods are used to determine the MIC, or the lowest concentration of antimicrobial agent required to inhibit the growth of the bacterium. Various concentrations of an antimicrobial agent are added to broth or agar media. Generally, serial twofold-dilution concentrations are tested (expressed in micrograms per milliliter). Concentrations chosen are those that are attainable in vivo following standard dosing of the antimicrobial agent. Because the concentration attainable in vivo differs with different agents, the ranges of concentrations tested also differ. For example, sustained concentrations greater than $8\mu\text{g/mL}$ for gentamicin and tobramycin cannot be safely attained in the patient; therefore the concentrations tested are generally in the range of 0.25 to $8.0\mu\text{g/mL}$. In contrast, much higher levels of the extended-spectrum penicillin, piperacillin, are attainable in vivo, and a range of 4 to $128\mu\text{g/mL}$ might be tested.

Once the MIC has been determined, the organism is interpreted as **nonsusceptible**, **susceptible**, **intermediate**, or **resistant** to each agent with the use of a table provided in the CLSI dilution testing document or in the FDA-approved package insert for the antimicrobial. *Susceptible* indicates that the bacteria are inhibited by achievable concentrations of the agent in vivo when the recommended dose is administered to

Fig. 13.2 Benchtop nephelometric-type devices can be used to standardize the turbidity of a test inoculum suspension to match that of a McFarland 0.5 turbidity (or other) standard.

treat an infection. *Intermediate* implies that antimicrobial MICs approach the usual blood and tissue levels, and response rates might be lower than for susceptible isolates. This applies to agents with lower toxicity that can be prescribed at higher-than-normal doses. *Resistant* implies that isolates are not inhibited by the usually achievable concentrations of the agent with normal dosage. *Nonsusceptible* is used for isolates for which only a susceptible breakpoint is designated because of the absence or rare occurrence of resistant strains. Both the FDA and the CLSI are involved in determining antimicrobial interpretive criteria for MIC test results. An example is shown in Table 13.1. Note that for some antimicrobial agents, different MIC interpretive criteria exist for different organisms or organism groups. For each antimicrobial agent, the MIC *breakpoint* separates susceptible from resistant results. Organisms with MICs at or below the breakpoint are susceptible, and those with MICs above that breakpoint are intermediate or resistant. Broth macrodilution, broth microdilution, and agar dilution methods are used for determining MIC values. These methods are briefly summarized in the following sections.

Antimicrobial stock solutions

Antimicrobial stock solutions used in MIC tests must be prepared from reference standard antimicrobial powders,

Table 13.1 Minimal inhibitory concentration interpretive standards for several organism groups ($\mu\text{g/mL}$)

Antimicrobial agent	Susceptible	Intermediate	Resistant
Ampicillin			
When testing Enterobacterales	≤ 8	16	≥ 32
When testing enterococci	≤ 8	—	≥ 16
When testing <i>Haemophilus</i> spp.	≤ 1	2	≥ 4
When testing viridans group streptococci	≤ 0.25	0.5–4.0	≥ 8
Gentamicin			
When testing Enterobacterales	≤ 4	8	≥ 16
When testing <i>Pseudomonas aeruginosa</i>	≤ 4	8	≥ 16
When testing staphylococci	≤ 4	8	≥ 16
Oxacillin			
When testing <i>Staphylococcus aureus</i>	≤ 2	—	≥ 4
When testing coagulase-negative staphylococci	≤ 0.5	—	≥ 1

not from the pharmaceutical preparations administered to patients. Details of preparation are found in the CLSI protocols. Stock drug solutions must be stored frozen in non-frost-free freezers. Temperature at or below -60°C is optimal and necessary for more temperature-labile drugs such as imipenem and clavulanic acid; however, -20°C storage is acceptable for some agents. Antimicrobial solutions are not to be refrozen after thawing.

Broth macrodilution (tube dilution) tests

Broth dilution MIC tests performed in test tubes are referred to as broth macrodilution MIC or tube dilution MIC tests. Generally, a twofold serial dilution series, each containing 1 to 2 mL of antimicrobial agent, is prepared. Mueller-Hinton broth is the medium recommended for broth dilution MIC tests of nonfastidious bacteria. A standardized suspension of test bacteria is added to each dilution to obtain a final bacterial concentration of 5×10^5 CFU/mL. A growth control tube (broth plus inoculum) and an uninoculated control tube (broth only) as a sterility check are used with each assay. After overnight incubation at 35°C , the MIC is determined visually as the lowest concentration that inhibits growth, as demonstrated by the absence of turbidity.

Broth macrodilution is impractical for use as a routine method when several antimicrobial agents must be tested on an isolate or if several isolates must be tested. Some laboratories use broth macrodilution when it is necessary to test drugs not included in their routine test system or for fastidious bacteria that require special growth media. Also, this method can be used when **minimum bactericidal concentration (MBC)** end points are to be determined subsequently. The MBC test is discussed later in this chapter.

Broth microdilution tests

The broth macrodilution test has been miniaturized and adapted to multiwell microdilution trays (Fig. 13.3) for broth microdilution MIC testing. Plastic trays contain between 80 and 100 (usually 96) wells. Wells are filled with small volumes (usually 0.1 mL) of twofold dilution concentrations of antimicrobial agent in broth. Because of the large number of

Fig. 13.3 Broth microdilution minimal inhibitory concentration (MIC) tray shown with an inoculum reservoir trough. A diluted inoculum suspension is placed in the reservoir trough. Then the prongs are dipped into the suspension, raised, and subsequently lowered into the wells of the broth microdilution MIC tray to inoculate all wells simultaneously.

wells, several dilutions of as many as 12 to 15 antimicrobial agents can be contained in a single tray that subsequently will be inoculated with one bacterial isolate. The inoculum suspension is prepared and standardized, as described earlier. An intermediate dilution of this inoculum suspension is prepared in water or saline, and a multipronged inoculator or other type of inoculating device is used to inoculate the wells to obtain a final concentration of approximately 5×10^5 CFU/mL (5×10^4 CFU/0.1-mL well). The actual dilution factor used for preparation of the intermediate dilution depends on the volume of inoculum delivered to each well by the inoculating device and the organism being tested. An example of this calculation is illustrated in Table 13.2. A growth control well and uninoculated control well are included on each tray. After overnight incubation at 35° C, the tray is placed on a tray-reading device to facilitate visual examination of each well (Fig. 13.4). Provided growth is adequate in the growth control well, the MIC for a particular drug is the lowest concentration showing no obvious growth.

Table 13.2 Sample calculations of dilution schema for preparation of inocula for broth microdilution minimal inhibitory concentration tests^a

Step	Resulting organism concentration
1. Standardize suspension to McFarland 0.5 standard	1.5×10^8 CFU/mL
2. Add 0.75 mL from step 1 to 25 mL water diluent (1:33 dilution)	$(4-5) \times 10^6$ CFU/mL
3. Use inoculator prong set to inoculate wells of MIC tray (each prong delivers 0.01 mL, which results in an additional 1:100 dilution)	$(4-5) \times 10^4$ CFU/100-μL well $(4-5) \times 10^5$ CFU/mL

^aCalculations shown here are based on use of inoculator prong set (each prong delivers 0.01 mL). Dilutions in step 2 differ, depending on the number of organisms in the initial suspension and the volume delivered to each well by the inoculating device.
CFU, Colony-forming units; MIC, minimal inhibitory concentration.

Fig. 13.4 Tray-reading stand with magnifying mirror (left) and light box (right). Following incubation, either of these devices is used to examine growth in the broth microdilution minimal inhibitory concentration trays. A tray is placed on the tray-reading stand, and wells are examined by looking into the magnifying mirror. A tray is placed over the hole in the light box, and light is allowed to shine through the tray to facilitate close examination of the wells.

Growth may be seen as turbidity, a haze, or a pellet in the bottom of the well. Results for quality control (QC) organisms should be read before reading results for patient isolates to determine whether the test was performed correctly.

Some laboratories use dispensing devices to prepare broth microdilution panels, but most laboratories purchase commercially prepared panels, frozen or freeze-dried. Commercially prepared panels must be stored and prepared for use as indicated by the manufacturer. Generally, frozen panels are thawed at room temperature just before inoculation. For dried panels, the dried or lyophilized drugs in the wells are reconstituted when the panels are inoculated. In addition to the panels, all manufacturers sell other materials needed for testing (e.g., inoculum broths, inoculum diluents, panel inoculators, reading devices). Usually, a variety of panels containing different drugs are available for testing various organism groups (e.g., gram-positive, gram-negative), and some panels are designed to include wells containing various biochemical reagents so organism identification and antimicrobial susceptibility testing can be done simultaneously in a single panel. Some companies have automated or semi-automated devices to facilitate inoculation and reading. These are discussed in the following sections.

Breakpoint (cutoff) minimal inhibitory concentration testing

A variation of the standard broth microdilution MIC panel is the inclusion of breakpoint testing, in which only one or a few concentrations of certain antimicrobial agents are tested on a single panel, in addition to standard MIC testing on other drugs. **Breakpoint (cutoff)** is the term applied to the concentration of an antimicrobial agent that coincides with a susceptible or intermediate MIC breakpoint for a particular drug. When two concentrations are tested and no growth is present in either well, the isolate is susceptible. When there is growth in the low concentration but no growth in the high concentration, the isolate has intermediate susceptibility, and a resistant isolate grows in both wells. The qualitative interpretation—nonsusceptible, susceptible, intermediate, or resistant—rather than an MIC value is reported. The primary advantage of breakpoint over full MIC testing for a drug is that a greater number of drugs can be tested on a single panel because a smaller number of wells is needed. The primary disadvantage of breakpoint testing is that a precise MIC is not obtained. Standalone breakpoint panels are generally not currently used clinically.

Trailing growth and skipped wells

Dilution methods sometimes produce an MIC end point that is not clear-cut, and growth in the wells may demonstrate trailing or skipped wells. **Trailing** involves heavy growth at lower concentrations followed by one or more wells that show greatly reduced growth in the form of a small button or a light haze. This commonly occurs with sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole; the mode of action of the agents allows the bacterial cells to grow through several generations before inhibition. In this case the trailing is ignored, and the end point is read as an 80% reduction in growth compared with the growth control. Trailing with most other drugs may represent contamination and should not be ignored unless it is known that trailing commonly occurs with the antimicrobial agent–organism combination.

Skipped wells involve growth at higher concentrations and no growth at one or more of the lower concentrations. This may occur because of contamination, improperly inoculated wells, improper concentrations of antimicrobial agent in the wells, the presence of unusual resistance with the test isolate (e.g., a small resistant subpopulation), or a combination of two or more of these factors. As with trailing, each skipped well occurrence must be evaluated individually to determine whether results are reportable. If any doubt exists about the validity of the results, they should not be reported, and the test should be repeated.

One shortcoming of the broth microdilution MIC method is its inability to produce a penicillin MIC that is consistently within the resistant range for staphylococci that are low-level, β -lactamase producers. If the penicillin MIC is $0.03\mu\text{g/mL}$ or lower, the isolate may be reported as penicillin-susceptible; a result of $0.25\mu\text{g/mL}$ or higher is considered resistant. It is recommended that an induced β -lactamase test be performed on isolates with penicillin MICs of 0.06 to $0.12\mu\text{g/mL}$. If the β -lactamase test result is positive, the isolate is reported as penicillin-resistant; if the result is negative, the isolate is reported as penicillin-susceptible.

Agar dilution tests

The MIC can also be determined using an agar dilution method. Specific volumes of antimicrobial solutions are dispensed into premeasured volumes of molten agar, which is subsequently poured into standard Petri dishes and then cooled. Mueller-Hinton agar is recommended for testing aerobic isolates; however, this can be supplemented with sheep's blood, to a final concentration of 5% sheep blood, or other nutrients for testing fastidious bacteria. A series of plates containing various concentrations of each antimicrobial agent and growth control plates without antimicrobial agent are prepared. A standard number of test bacteria (10^4 CFU for aerobes) are spot-inoculated onto each plate using a multi-pronged replicating device (Fig. 13.5). As many as 32 different

Fig. 13.5 Steer's replicator. The inoculator prongs are positioned above a 36-well seed trough that contains 36 different standardized inoculum suspensions. The handle on top of the prong unit is pressed to lower the prongs into all suspensions simultaneously, and when the prongs are raised, each contains a standardized volume of inoculum. The agar plate containing a defined concentration of antimicrobial agent is positioned under the prongs (the steel plate holding the agar plate slides back and forth), and the prongs are carefully lowered to the agar, at which point the inocula are deposited on the agar surface. This process is repeated until all antimicrobial-containing and control agar plates (without antimicrobial agent) have been inoculated.

isolates can be simultaneously inoculated onto each 100-mm round Petri dish; 100-mm square plates generally accommodate 36 isolates. After overnight incubation, the MIC is read as the lowest concentration of antimicrobial agent that inhibits the visible growth of the test bacterium (one or two colonies are ignored).

The shelf life of agar dilution plates is only 1 week for most antimicrobial agents stored at 2° to 8°C because many drugs are labile in this temperature range. Because plate preparation is laborious and this procedure is practical only if large numbers of isolates are tested, agar dilution is generally performed in research settings, although it is currently considered the primary method for antimicrobial susceptibility testing of obligate anaerobes and is the only accepted reference method for *Neisseria gonorrhoeae* and *Helicobacter pylori*.

Disk diffusion testing

Principle

The disk diffusion test, commonly known as the **Kirby-Bauer test**, has been widely used in clinical laboratories since 1966, when the first standardized method was described. Briefly, a McFarland 0.5 standardized suspension of bacteria (as described in Inoculum Preparation earlier) in Mueller-Hinton broth is swabbed over the surface of a standardized Mueller-Hinton agar plate, and paper disks containing specific concentrations of antimicrobial agent are placed onto the inoculated surface. After incubation of 16 to 18 hours, the diameters of the zones of inhibition around each disk are measured. The result is interpreted as nonsusceptible, susceptible, intermediate, or resistant to a particular drug according to preset criteria. This method has been standardized for common, rapidly growing bacteria; it should not be used for slowly growing bacteria and obligate anaerobes. An isolate of *Klebsiella* (*Enterobacter*) *aerogenes* tested by disk diffusion is shown in Fig. 13.6.

Fig. 13.6 *Klebsiella* (*Enterobacter*) *aerogenes* tested by the disk diffusion method. Zone measurements confirm that the isolate is susceptible to all agents tested, except ampicillin (at the 1-o'clock position) and cefazolin (at the 2-o'clock position). No zones are present for either of these agents.

Establishing zone diameter interpretive breakpoints

The disk diffusion test depends on the formation of an antimicrobial concentrations gradient as the antimicrobial agent radially diffuses into the agar. The drug concentration decreases at increasing distances from the disk. At a critical point, the amount of drug at a specific location in the medium is unable to inhibit the growth of the test organism, and a **zone of inhibition** is formed.

The zones of inhibition are related to MICs, and this relationship is used to determine the breakpoints for interpreting a particular zone measurement indicating that the isolate is nonsusceptible, susceptible, intermediate, or resistant. To establish breakpoints for a single agent, the first step is to determine the optimum concentration of drug to incorporate into the disk, which considers the drug's pharmacokinetic properties and some of its biochemical properties (e.g., molecular size, solubility, diffusibility in agar). Next, a sample of 150 to 200 isolates with comparable growth rates and differing susceptibility to the agent are tested by the disk diffusion test and a dilution MIC test, and results are plotted on a graph. For each isolate, the observed MIC is expressed in logarithmic form ($\log_2$) and plotted on the *y*-axis, and the corresponding zone measurement is plotted on the *x*-axis on an arithmetic scale (scattergram; Fig. 13.7). Zone diameter breakpoints are then selected based on a comparison of the susceptible, intermediate, and resistant MIC breakpoints with the zone diameters, while considering the typical in vivo achievable concentrations from standard dosing. The best zone diameter breakpoints are chosen to categorize isolates correctly with minimal interpretive errors.

With some of the newer, extremely potent drugs, resistant isolates may not presently exist, so only a susceptible criterion is defined; no intermediate- or resistant-zone interpretive criteria are specified. Further tests, possibly in a reference laboratory, should be performed on any isolate that is interpreted

Fig. 13.7 Scattergram and regression analysis plot used to determine disk diffusion zone diameter interpretive breakpoints for hypothetical drug X. Based on clinical response data, isolates with a minimal inhibitory concentration (MIC) of $8.0 \mu\text{g/mL}$ or less are considered susceptible. As derived from this scattergram, corresponding zones of 20 mm or more would be interpreted as susceptible. Isolates with MICs of $32.0 \mu\text{g/mL}$ or more and zones of 11 mm or less are resistant. The intermediate designation is used for isolates whose values fall between the susceptible and the resistant MIC ($16 \mu\text{g/mL}$) and zone interpretive breakpoint (12 to 19 mm).

as other than susceptible (nonsusceptible) when only susceptible or nonsusceptible criteria are specified for the particular antimicrobial agent–organism combination.

Test performance

Most clinical laboratories follow the protocol specified by the CLSI for disk diffusion testing. The CLSI document contains explicit details for test performance.

Disk storage

Disks must be stored properly to ensure that the drugs maintain their potency. For long-term storage, disks are stored at -20°C or below in a non-frost-free freezer. A working supply of disks can be stored in a refrigerator at 2° to 8°C for at least 1 week. Disks should always be stored in a tightly sealed container with desiccant. The container should be allowed to warm to room temperature before it is opened to prevent condensation from forming on the disks when warm room air contacts the cold disks. Only FDA-cleared disks should be used.

Inoculation and incubation

Inoculum suspensions are prepared using a log phase or direct colony suspension to match the turbidity of a McFarland 0.5 standard, as described earlier. A sterile swab is dipped into the suspension, pressed and rotated firmly against the side of the tube to express excess liquid, and then swabbed evenly across the surface of a Mueller-Hinton agar plate. The plate should be swabbed two more times, turning the plate 60 degrees each time, using the same swab (*without* going back into the suspension) to ensure an even “lawn” of bacteria on the plate. Commercially manufactured plate inoculators are available as well (e.g., bioMérieux, Durham, NC). Usually, a plate 150 mm in diameter is used; it can accommodate testing of as many as 12 different antimicrobial disks with most bacteria; placement of more than 12 disks on the plate can result in overlapping zones, which are difficult to measure and may produce erroneous results. At the same time, it is recommended that a “purity plate” (usually sheep blood agar, or chocolate agar for more fastidious organisms) be inoculated from the swab so the next day when results are checked, it can be visually determined with certainty that the isolate was pure on the lawn plate.

Within 15 minutes of inoculation, the antimicrobial disks are applied to the agar individually with sterile forceps or with a multiple-disk dispenser (Fig. 13.8). The disks are pressed firmly to ensure contact with the agar. Within 15 minutes of disk placement, the plates are inverted and placed in a 35°C ambient air incubator for 16 to 18 hours. Although incubation in an atmosphere of increased carbon dioxide (CO_2) is recommended for testing some fastidious bacteria, this should not be done with most organisms. Incubation in CO_2 results in a decreased pH, which affects the activity of some antimicrobial agents.

Reading plates

After incubation, the purity plate is visually inspected to confirm a pure culture was tested. QC plates are read before reading results of patient isolates to determine if the test was performed correctly. The test plate is examined to ensure that the organism grew satisfactorily. The lawn of growth must

Fig. 13.8 Cartridges containing antimicrobial susceptibility test disks are inserted into the dispenser (left). The dispenser (which can hold up to 12 different cartridges of disks) is positioned over an inoculated plate, and light pressure is applied to the handle to simultaneously deposit one of each type of disk onto the plate. The tight-sealing container in the background contains a desiccant packet and is used for storage (at 2° to 8° C) of the dispenser containing a working supply of disks.

Fig. 13.9 *Escherichia coli* tested by the disk diffusion method. The lawn of growth following overnight incubation shows individual colonies, representing unsatisfactory growth. The most likely explanation for the scanty growth is the use of an inoculum that is too light or contains too many nonviable cells, resulting in larger than normal zones and potentially false-susceptible results.

be confluent or almost confluent. The appearance of individual colonies is unacceptable (Fig. 13.9). If growth is satisfactory, the diameter of each inhibition zone is measured using a ruler, or preferably calipers. Plates are placed a few inches above a black, nonreflecting surface, and zones are examined from the back side (agar side) of the plate illuminated with reflected light (Fig. 13.10). Tiny colonies at the zone edge and

Fig. 13.10 Routine disk diffusion tests are examined by placing the plate on or 2 to 3 inches above a black nonreflecting surface. Reflected light is used to illuminate the plate.

swarm of growth into the zone that often occurs with swarming *Proteus* spp. are ignored; the obvious zone is measured.

As with dilution tests, the end point for the sulfonamides, trimethoprim, and trimethoprim-sulfamethoxazole is an 80% reduction of growth. Obvious colonies within a clear zone should not be ignored. These colonies may occur because of contamination or testing of a mixed culture; however, these colonies sometimes represent a minority resistant subpopulation. When such colonies are noted, the original isolate should be retested. If repeated testing produces the same results, the isolate should be reported as resistant.

Transmitted light (plate held up to a light source; Fig. 13.11) rather than reflected light will increase the accuracy of tests with the **penicillinase-resistant penicillins** linezolid and vancomycin when testing staphylococci and for vancomycin when testing enterococci. Automated disk diffusion zone reading devices, such as BIOMIC (Giles Scientific USA, Santa Barbara, CA), that recognize disk codes and interpret zones digitally are available. The advantages of these devices include speed of analysis in high-volume laboratories and the capacity to store QC and patient isolate images.

Once zone measurements have been made, the millimeter reading for each antimicrobial agent is compared with that specified in the interpretive tables of the CLSI documents or FDA drug package insert, and results are interpreted as susceptible, nonsusceptible, intermediate, or resistant. An excerpt from the chart is shown in Table 13.3. The equivalent MIC breakpoints that are used to define resistance and susceptibility are also shown. Note that as with MIC interpretive criteria, several sets of interpretive criteria that are specific for various organisms or organism groups may exist for some antimicrobial agents.

Fig. 13.11 Disk diffusion tests for staphylococci with oxacillin and vancomycin and for enterococci with vancomycin are examined by holding the plate up to a light source (transmitted light) for zone examination. Any growth within the zone is significant.

Interpretation of in vitro antimicrobial susceptibility test results

Several elements are important when performing in vitro antimicrobial susceptibility tests. A summary of the variables that must be carefully controlled in the performance of disk diffusion and broth microdilution MIC tests is given in Table 13.4. The procedural steps of each method must be followed explicitly to obtain reproducible results. A susceptibility test should never be performed using an inoculum that is not standardized or a mixed culture. For this reason, direct susceptibility tests that incorporate the use of a patient's infected body fluid cannot be recommended, even to obtain a presumptive result. Direct detection of drug resistant genes is a much better option.

The results of a susceptibility test must be interpreted in the laboratory before a report is communicated to a patient's physician. With a disk diffusion test, the inhibition zone size must be interpreted using a table of values that relates the diameter of the zone of inhibition to a category of susceptibility, which is sometimes related to the identity of the isolate. The table used for such interpretations must represent the most recent criteria that have been established by the CLSI. It is important to recognize that the CLSI documents are updated frequently, often annually. Use of old or outdated CLSI tables could represent a serious shortcoming in patient care.

The inhibition zone size and MIC interpretive criteria published by the CLSI and FDA are established by careful

Table 13.3 Zone diameter interpretive standards and equivalent minimal inhibitory concentration breakpoints for several organism groups

Antimicrobial agent	Disk content (μg)	Zone diameter (nearest whole mm)			Equivalent MIC breakpoints (μg/mL)	
		Resistant	Intermediate	Susceptible	Resistant	Susceptible
Ampicillin						
When testing Enterobacterales	10	≤13	14–16	≥17	≥32	≤8
When testing enterococci	10	≤16	—	≥17	≥16	≤8
When testing <i>Haemophilus</i> spp.	10	≤18	19–21	≥22	≥4	≤1
When testing β-hemolytic streptococci	10	—	—	≥24	—	≤0.25
Gentamicin						
When testing Enterobacterales	10	≤12	13–14	≥15	≥16	≤4
When testing <i>Pseudomonas aeruginosa</i>	10	≤12	13–14	≥15	≥16	≤4
When testing staphylococci	10	≤12	13–14	≥15	≥16	≤4
Oxacillin						
When testing <i>Staphylococcus aureus</i>	30 Surrogate: cefoxitin	<21		>22	≥4 (ox) >8 (cefoxitin)	≤2 (ox) <4 (cefoxitin)
When testing <i>Streptococcus pneumoniae</i> (nonpneumonia isolates) for penicillin susceptibility	1		—	≥20	—	≤0.06

Table 13.4 Primary variables that must be controlled in performance of routine disk diffusion and broth microdilution minimal inhibitory concentration tests

Variable	Standard	Comments
Inoculum	Disk diffusion: 1.5×10^8 CFU/mL Broth microdilution: 5×10^5 CFU/mL (final concentration)	Use "adequate" McFarland turbidity standard (0.5 for disk diffusion) When preparing direct suspensions (without incubation), do not use growth from plates >1 day old
Media		
Formulation	Mueller-Hinton	Prepare in house or purchase from reliable source Perform media quality control to verify acceptability before use for patient tests
Ca ²⁺ , Mg ²⁺ content	25 mg/L Ca ²⁺ , 12.5 mg/L Mg ²⁺	Increased concentrations result in decreased activity of aminoglycosides against <i>Pseudomonas aeruginosa</i> and decreased activity of tetracyclines against all organisms (decreased concentrations have the opposite effect)
Thymidine content	Minimal or absent	Excessive concentrations can result in false resistance to sulfonamides and trimethoprim
pH	7.2–7.4	Decreased pH can lead to decreased activity of aminoglycosides, erythromycin, and clindamycin and increased activity of tetracyclines (increased pH has the opposite effect)
Agar depth (disk diffusion)	3–5 mm	Possibility for false susceptibility if <3 mm or false resistance if >5 mm
Incubation		
Atmosphere	Humidified ambient air	CO ₂ incubation decreases pH, which can lead to decreased activity of aminoglycosides, erythromycin, and clindamycin and increased activity of tetracyclines
Temperature	35° C	Some MRSA may go undetected if >35° C
Length	Disk diffusion: 16–18 hours	Some MSRA may go undetected if <24 hours
	Broth microdilution: 16–20 hours	Some vancomycin-resistant enterococci may go undetected if <2 hours with disk diffusion
	24 hours for staphylococci with oxacillin ^a and vancomycin and for enterococci with vancomycin and gentamicin HLAR; 48 hours for enterococci with streptomycin HLAR; 24 hours sometimes needed for fastidious bacteria	Some HLAR (gentamicin) enterococci may go undetected if <24 hours (broth microdilution) Some HLAR (streptomycin) enterococci may go undetected if <48 hours (broth microdilution)
Antimicrobial agents		
Disks	Use disks containing appropriate FDA- or CLSI-defined concentration of drug	Check CLSI publication or FDA package insert (accompanying disks) for specifications.
	Proper storage	For long-term storage, use non-frost-free freezer at –20° C or less in a tightly sealed, desiccated container For short-term storage (at least 1 week), maintain temperature at 2° to 8° C in a tightly sealed, desiccated container Allow to warm to room temperature before opening container
	Proper placement on agar	Place 12 or fewer disks/150-mm plate (no overlapping zones)
Solutions	Prepared from reference standard powders	Pharmacy-grade antimicrobial agents unacceptable (may not show antimicrobial activity in vitro)
	Proper storage	Store in non-frost-free freezer, optimally at –70° C or less Never refreeze
End point measurement		
Disk diffusion	Reflected light (except for staphylococci with oxacillin ^a and vancomycin, and for enterococci with vancomycin) and plate held against black background	Lawn must be confluent or almost confluent Ignore faint growth of tiny colonies at zone edge
	Zones measured from back of plate	Trimethoprim and sulfonamide end point at 80% or more inhibition Ignore swarm within obvious zone for swarming <i>Proteus</i> spp Retest when colonies are within zone (except for staphylococci with oxacillin, and enterococci with vancomycin)
	Transmitted light used for staphylococci with oxacillin ^a and vancomycin, and for enterococci with vancomycin	Call <i>resistant</i> if any growth within zone (unless possibly artifactual or contaminated) Reproducibility of zone measurements is within ± 2 mm

Continued

Table 13.4 Primary variables that must be controlled in performance of routine disk diffusion and broth microdilution minimal inhibitory concentration tests—Cont'd

Variable	Standard	Comments
Broth microdilution	Adequate lighting and reading device	MIC is the lowest concentration that inhibits growth (turbidity, haze, or pellet) Sulfonamides and trimethoprim may trail (ignore trailing <2-mm buttons) Justify "skip wells" or repeat Staphylococci and penicillin: perform induced β -lactamase test if MIC = 0.06–0.12 μ g/mL Reproducibility should be within ± 1 twofold dilution
^a Includes all penicillinase-resistant penicillins (oxacillin, methicillin, nafcillin, and dicloxacillin). CFU, Colony-forming units; CLSI, Clinical and Laboratory Standards Institute; FDA, U.S. Food and Drug Administration; HLAR, high-level aminoglycoside resistance; MIC, minimal inhibitory concentration; MRSA, methicillin-resistant <i>Staphylococcus aureus</i> . Modified from Hindler, J. A., & Mann, L. M. (1992). Principles and practices for the laboratory guidance of antimicrobial therapy. In R. C. Tilton, et al. (Eds.), <i>Clinical laboratory medicine</i> . St. Louis: Mosby.		

analysis of three types of data: (1) microbiological data (e.g., a comparison of MICs vs. zone sizes on a large number of bacterial strains, including those with known resistance mechanisms); (2) pharmacokinetic data (e.g., serum, cerebrospinal fluid [CSF], urine, and other body fluids and tissue levels of an antimicrobial agent); and (3) results of clinical studies obtained before FDA approval and marketing of an antimicrobial agent. Thus MIC interpretive criteria are not based simply on a comparison of serum levels of an antimicrobial agent and MICs. Zone diameter interpretive criteria are, however, based largely on direct correlations of MICs and zone sizes.

Whether based on the determination of an MIC or on interpretation of a disk diffusion zone diameter, the four categories of susceptibility should be interpreted in the same manner. If the MIC or zone size is interpreted as susceptible using the most recent interpretive criteria, the clinical interpretation of the result is that the patient's infecting organism should respond to therapy with that antimicrobial agent using the recommended dosage for the site of infection. Conversely, an MIC or zone size interpreted as resistant is unlikely inhibit the bacterium by the usually achievable concentrations of the antimicrobial agent based on the normal dosages used with that drug. An intermediate result indicates that a bacterium falls into a range of susceptibility in which the MIC approaches or exceeds the level of antimicrobial agent that can ordinarily be achieved, and for which clinical response is likely to be less than with a susceptible strain. Exceptions can occur if the antimicrobial agent is highly concentrated in a body fluid, such as urine, or if a higher-than-normal dosage of the antimicrobial agent can be safely administered (e.g., some penicillins and cephalosporins). At times, the intermediate result means that certain variables in the susceptibility test may not have been well controlled, and the values have fallen into a zone, separating susceptible from resistant strains.

Another category that may be used for reporting is *non-susceptible*. This category is used when there are no intermediate or resistant interpretive criteria, only a susceptible interpretive criterion, and the MIC or disk diffusion zone size for classifying the organism as susceptible is not achieved. In these cases, the identity of the organism should be confirmed and susceptibility testing repeated. If the results are still nonsusceptible, it may be appropriate to send the bacterium to a reference laboratory. The nonsusceptible category commonly occurs with newer antimicrobials because during

drug development and initial clinical trials, no organisms were found that were resistant to the agent. The category nonsusceptible does not necessarily mean that the organism is resistant to the antimicrobial.

Certain other specific aspects of susceptibility test reporting are detailed in the CLSI tables, such as refraining from reporting results for antimicrobial agents that do not enter the CSF on isolates from patients who have meningitis. Also, results for antimicrobial agents that are only useful for treating UTIs must not be reported on isolates from specimens other than urine.

Modified test methods for slow-growing or fastidious bacteria

Mueller-Hinton broth and agar are the standard media used for routine dilution and disk diffusion susceptibility tests. These media, however, do not support the growth of all bacteria that require testing; consequently, routine methods must be modified for testing fastidious bacteria that require supplemental nutrients, modified incubation conditions, or both.

Streptococcus species

Streptococcus spp., including *Streptococcus pneumoniae*, require a more nutritious medium for growth; they will not grow satisfactorily on unsupplemented Mueller-Hinton medium. Broth dilution tests are performed in Mueller-Hinton broth that has been supplemented with 2% to 5% lysed horse blood. The standard disk diffusion procedure uses Mueller-Hinton agar supplemented with 5% sheep blood incubated in 5% CO₂ for 20 to 24 hours. Tests performed on media containing blood are examined from the top of the plate with the lid removed. For plates containing blood, it is important to read the zone of growth inhibition and not the zone of hemolysis.

Penicillins and cephalosporins remain the drugs of choice for treating pneumococcal infections; however, resistance to penicillin and to other potentially useful agents is widespread. Penicillin resistance in *S. pneumoniae* is caused by the presence of altered penicillin-binding proteins (drug targets in the cell wall). It is possible to screen for penicillin susceptibility in *S. pneumoniae* using an oxacillin disk (1 μ g), except on isolates from blood or CSF, in which case penicillin MIC

Fig. 13.12 An oxacillin (1- μ g) disk is used to screen for penicillin susceptibility in *Streptococcus pneumoniae* isolated from specimens other than cerebrospinal fluid and blood. If the oxacillin zone of inhibition is 20 mm or larger from a non meningitis isolate, it is reported as penicillin susceptible. If the oxacillin zone is 19 mm or smaller, a penicillin minimal inhibitory concentration (MIC) test must be performed. The isolate pictured has an oxacillin zone of approximately 15 mm, so a penicillin MIC test must be performed.

testing must be performed. A penicillin disk should not be used for screening purposes because it is less accurate. If the oxacillin zone of inhibition is 20 mm or larger, the isolate can be safely reported as penicillin (not oxacillin) susceptible (penicillin MIC $\leq 0.06 \mu\text{g/mL}$). If the oxacillin zone is 19 mm or smaller, a penicillin (not oxacillin) MIC test must be performed to determine the degree of resistance (Fig. 13.12).

S. pneumoniae isolates from non-CSF sites with penicillin MICs of $0.06 \mu\text{g/mL}$ or less are interpreted as susceptible, with penicillin MICs of 0.12 to $1.0 \mu\text{g/mL}$ as intermediate, and with penicillin MICs of $2.0 \mu\text{g/mL}$ or more as resistant when orally administered penicillin V is to be used for treatment. When parenterally administered penicillin is to be used for treatment of isolates from non-CSF sources (e.g., from sputum), the isolate is considered susceptible when the MIC is $2 \mu\text{g/mL}$ or less, intermediate when the MIC is $4 \mu\text{g/mL}$, and resistant when the MIC is $8 \mu\text{g/mL}$ or more. If the *S. pneumoniae* isolate is from CSF, the isolate is considered susceptible to penicillin when the MIC is $0.06 \mu\text{g/mL}$ or less and resistant when the MIC is $0.12 \mu\text{g/mL}$ or more. Determining the degree of penicillin resistance is important because the recommended therapy may be different for penicillin-intermediate and penicillin-resistant strains. It is important to test penicillin-resistant isolates with other clinically relevant antimicrobial agents, such as cefotaxime or ceftriaxone (by an MIC method, not disk diffusion), erythromycin, a fluoroquinolone, vancomycin, and perhaps clindamycin or a tetracycline.

The methods for testing nonpneumococcal streptococci are the same as those for *S. pneumoniae*; however, separate breakpoints for this group of bacteria have been defined. β -hemolytic streptococci remain universally susceptible to penicillin, the drug of choice for treating infections caused by these organisms; therefore routine susceptibility testing on β -hemolytic streptococci is generally not necessary. For penicillin-allergic patients, alternative agents for therapy include a macrolide (e.g., erythromycin) or clindamycin. In contrast with penicillin, some β -hemolytic streptococci are resistant to erythromycin only or to erythromycin and clindamycin. Isolates that appear erythromycin-resistant and clindamycin-susceptible may have inducible or constitutive resistance to clindamycin. Before reporting clindamycin as susceptible in these cases, a **D-zone test** must be performed, as described later in this chapter for staphylococci.

Accurate penicillin susceptibility results are needed for viridans streptococci isolated from serious infections such as bacteremia or endocarditis. If the isolate has a penicillin MIC of $0.12 \mu\text{g/mL}$ or less, penicillin alone is often prescribed; however, higher penicillin MICs (0.25 to $2.0 \mu\text{g/mL}$) suggest the need for concomitant therapy with an aminoglycoside. Isolates with penicillin MICs greater than $2.0 \mu\text{g/mL}$ are highly resistant, and for these isolates, vancomycin rather than penicillin is generally prescribed. Because of the critical nature of penicillin susceptibility results, the disk diffusion test is not recommended; instead, MIC tests should be performed. As with *S. pneumoniae*, penicillin resistance in viridans streptococci is caused by altered penicillin-binding proteins.

Haemophilus influenzae and Haemophilus parainfluenzae

Haemophilus test medium (HTM), which consists of Mueller-Hinton base supplemented with X (hematin) and V (nicotinamide adenine dinucleotide [NAD]) factors, has been standardized for testing *Haemophilus influenzae* and *Haemophilus parainfluenzae*. HTM broth is used for broth dilution tests, and HTM agar is used for disk diffusion tests. The procedures for *Haemophilus* spp. are identical to those described for nonfastidious bacteria, with the exception that the disk diffusion test with HTM is incubated in an atmosphere of 5% to 7% CO_2 . Zone diameter and MIC interpretive criteria unique for this genus are available. For some agents, such as cefotaxime, only a susceptible range is defined because cefotaxime-resistant *Haemophilus* spp. have not been identified. In cases in which the determined MIC is greater than what would make the organism cefotaxime-susceptible, the organism is reported as nonsusceptible. In these cases, the organism should be reidentified and the MIC redetermined. If the same results are obtained after retesting, the organism should be submitted to a reference laboratory, such as a state health laboratory.

Ampicillin or amoxicillin is often effective in treating localized, less serious *H. influenzae* infections; however, 25% to 50% of *H. influenzae* isolates produce a β -lactamase that inactivates these agents. β -Lactamase-producing isolates can be quickly identified by using a rapid β -lactamase bench test. *H. influenzae* also may be resistant to ampicillin and amoxicillin because of altered penicillin-binding proteins. These isolates are referred to as β -lactamase-negative, ampicillin-resistant (BLNAR). This resistance occurs in less than 1.0% of clinical isolates in the United States but is higher in other countries, such as Japan. Very small proportions of isolates possess resistance caused by altered penicillin-binding proteins and production of β -lactamase and are referred to as β -lactamase-positive, amoxicillin-clavulanate-resistant (BLPACR) isolates. The BLNAR and BLPACR isolates are both detectable only by in vitro susceptibility testing. There are no rapid detection methods for these types of resistance. Because most ampicillin-resistant (amoxicillin-resistant) *H. influenzae* isolates produce β -lactamase, and *H. influenzae* is often susceptible to alternative agents currently recommended, some laboratories only perform a β -lactamase test or test only ampicillin and trimethoprim-sulfamethoxazole by the disk diffusion or MIC method. However, they will test additional agents (e.g., fluoroquinolones) if the isolate is from nonrespiratory sources or if requested by clinicians.

Neisseria gonorrhoeae and *Neisseria meningitidis*

Neisseria gonorrhoeae and *Neisseria meningitidis* are of public health significance. Therapy for disseminated meningococcal infections and various types of gonococcal infections is generally empiric, based on recommendations from the Centers for Disease Control and Prevention (CDC) and various professional groups. Usually, clinical microbiology laboratories are not required to perform antimicrobial susceptibility testing of these two species. Public health laboratories, however, may receive requests to test them on a periodic basis. The CLSI has described MIC and disk diffusion methods for these species.

Penicillin was the drug of choice for treating uncomplicated gonorrhea. However, penicillin-resistant isolates emerged in the 1970s, and fluoroquinolone-resistant isolates emerged in the 1990s. This led to the current use of ceftriaxone or cefixime as first-line therapy. Penicillin resistance in *N. gonorrhoeae* can be caused by the production of a β -lactamase like that produced by ampicillin-resistant *H. influenzae*, and this resistance can be readily detected with a rapid β -lactamase test. β -Lactamase-producing isolates are referred to as **penicillinase-producing *Neisseria gonorrhoeae* (PPNG)**. Some *N. gonorrhoeae* isolates are penicillin resistant because of an altered penicillin-binding protein; this resistance can be detected only with conventional dilution or disk diffusion tests. The production of altered penicillin-binding proteins is chromosomally mediated, and *N. gonorrhoeae* with altered penicillin-binding proteins is often referred to as **chromosomally mediated resistant *Neisseria gonorrhoeae* (CMRNG)**.

Because of continuing changes in the susceptibility of *N. gonorrhoeae*, the need for testing the susceptibility of isolates in hospital laboratories may be necessary again after a hiatus for several years. Since the implementation and widespread use of rapid nucleic acid testing methods for *N. gonorrhoeae*, however, fewer isolates are grown in culture, making it difficult, unfortunately, to monitor these changes.

Gonococcal agar base is supplemented with various nutrients for testing *N. gonorrhoeae*. Dilution tests are performed using agar dilution because this species tends to lyse in broth media, resulting in false-susceptible results. Disk diffusion tests are performed on the same agar, and all tests are incubated in an atmosphere containing 5% to 7% CO₂. The CLSI and FDA have specified interpretive criteria unique for this species. For several agents, resistant isolates have not yet been encountered, so only susceptible criteria are available.

Except for very rare isolates that produce β -lactamase, *N. meningitidis* is generally susceptible to penicillin; however, in the United States, ceftriaxone or cefotaxime is usually the drug of choice for treating invasive meningococcal infections. Isolates with elevated penicillin MICs (penicillin-intermediate) have been reported, although their significance is minimized through the extensive use of third-generation cephalosporins for therapy. Meningococci are often resistant to sulfonamides (including trimethoprim-sulfamethoxazole) and are occasionally resistant to rifampin. For these reasons, a fluoroquinolone (e.g., ciprofloxacin) is usually administered prophylactically to individuals in close contact with patients with meningococcal meningitis. The CLSI has described MIC and disk diffusion methods for testing meningococci that are the same as those used for testing the streptococci, except that broth microdilution tests with meningococci require CO₂

incubation. Breakpoints for determining susceptibility or resistance in meningococci for several agents can be found in the latest CLSI tables.

Helicobacter pylori and *Campylobacter* species

The susceptibility of *H. pylori* to antimicrobials is best determined by agar dilution testing using Mueller-Hinton agar containing 5% aged (≥ 2 weeks old) sheep blood. Susceptibility test plates must be incubated in a microaerobic environment and read at 3 days of incubation. Genotypic tests in development for identification of the organism and resistance genes using polymerase chain reaction (PCR) assays and sequencing techniques directly from the specimen show promising results. *Campylobacter* spp. can also be tested using agar dilution, or broth microdilution and disk diffusion methods. CLSI guidelines detail specific procedures for testing for both genera, as well as the QC strains to use and interpretive criteria for specific antimicrobials.

Susceptibility testing of agents of bioterrorism

With the occurrence of the terrorist attacks in the United States on September 11, 2001, the more imminent threat of the use of bacteria and other pathogens as agents of bioterrorism was given heightened attention. Before this event, there were no standardized methods for testing the susceptibility of *Bacillus anthracis*, *Yersinia pestis*, *Burkholderia mallei*, *Burkholderia pseudomallei*, *Francisella tularensis*, and *Brucella* spp. to antimicrobials. In addition, knowledge was limited regarding the use of antimicrobials to prevent or treat infections caused by these bacteria. Since then, the CLSI has standardized the methods for susceptibility testing of these bacteria against a variety of antimicrobials and has established interpretive criteria for the results of these tests (publication M45). In addition, a great deal more information is now available on the use of antimicrobials that can be used to prevent infections with these organisms and to treat infections if they do occur. However, these organisms are an imminent danger when being tested in the laboratory, and work with these organisms should be conducted only in a biosafety level 2 (BSL2) or higher facility by trained individuals. This limitation applies even to routine susceptibility tests. As soon as it is suspected that a specimen may contain one of these agents or that one of these bacteria has been isolated, the specimen or isolate must be quarantined and sent to a state health laboratory after state health officials are alerted. Clinical laboratories should establish contingency plans to deal with situations in which bioterrorism agents have appeared, or potentially appeared, in the laboratory, especially if a staff member has been exposed and might need prophylaxis.

Obligate anaerobic bacteria

The reference method described by the CLSI for testing anaerobic bacteria is an agar dilution method, and the recommended medium is supplemented *Brucella* laked sheep blood agar. As noted, however, agar dilution is not practical for use in the routine clinical laboratory; a broth microdilution method is used more often. The CLSI broth microdilution procedure resembles that used for testing aerobes, except that *Brucella* broth with lysed horse blood is used for testing the

B. fragilis group of anaerobes. Also, the number of organisms in the test inoculum is $0.5 \log_{10}$ higher (10^6 CFU/mL) than that for testing aerobes, and panels are incubated anaerobically at 35° C for 48 hours. As with tests for aerobic bacteria, the CLSI has defined *susceptible*, *intermediate*, and *resistant* criteria for the interpretation of MICs for anaerobes. Several commercial companies produce broth microdilution MIC panels for testing anaerobes. The **Etest** (AB Biodisk, Solna, Sweden), discussed in detail later, has been shown to perform satisfactorily for susceptibility testing of anaerobes and is used in many clinical laboratories.

Infrequently encountered or fastidious bacteria

Besides anaerobes, the CLSI publication M45 focuses on infrequently encountered or fastidious bacteria not addressed in the standard MIC and disk diffusion documents. When clinically indicated, isolates of corynebacteria (and some other gram-positive bacilli), *Aeromonas*, *Vibrio*, *Pasteurella*, *Moraxella catarrhalis*, some members of the HACEK (*Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium* spp., *Eikenella corrodens*, and *Kingella* spp.) group of gram-negative bacteria, and *Abiotrophia* and *Granulicatella* can be tested using various standard CLSI methods; the results are interpreted using the CLSI tables specific for each organism. CLSI publication M24-A2 (2011) offers guidelines for antimicrobial testing of acid-fast bacilli, including *Mycobacterium tuberculosis*, nontuberculous mycobacteria (NTM), and *Nocardia*. Yeasts and filamentous fungi can be tested using agar dilution, standardized disk diffusion and Etest tests, broth macrodilution, and microdilution techniques. Some commercial automated systems can perform antifungal susceptibility testing of *Candida* spp. as well.

Additional organism and antimicrobial agent testing concerns

Special procedures must be used to detect clinically significant resistance in some nonfastidious bacteria.

Case check 13.2

Laboratories' procedures include ways of detecting drug resistance in all clinically significant microorganisms. The method must be determined to provide an accurate and reproducible result. It is important to know which assay to use and if modifications are necessary for unusual or fastidious isolates.

Detection of oxacillin (methicillin) resistance in staphylococci

Oxacillin and other penicillinase-resistant penicillins, such as methicillin, nafcillin, cloxacillin, and dicloxacillin, constitute the drug class of choice for treating staphylococcal infections. Oxacillin is the class representative generally used to detect resistance in staphylococci and has produced more reliable results than testing any of the other agents. When an isolate shows resistance to one of the penicillinase-resistant penicillins, it must be considered resistant to the entire group. Staphylococcal resistance to the penicillinase-resistant

penicillins is most often caused by the presence of a unique penicillin-binding protein (PBP2a or PBP2') in the cell wall. The *mecA* gene encodes an altered penicillin-binding protein, which has a low affinity for binding all β -lactam drugs. In addition, oxacillin resistance in staphylococci can be caused by the *mecC* gene, which has been recovered from isolates from livestock and humans with animal exposure, although the prevalence is currently low. The *mecC* gene has about 70% homology to *mecA* and codes for a PBP2a protein with only about 63% similarity to the *mecA* product. Therefore the PCR assay for *mecA* and the antigen tests for PBP2a will not detect *mecC* oxacillin resistance.

Although methicillin is no longer available, isolates of oxacillin-resistant *S. aureus* are commonly referred to as MRSA for historic reasons. Because some staphylococci exhibit heteroresistance or heterogeneous expression of resistance to oxacillin, detecting oxacillin resistance in isolates that possess the *mecA* gene has sometimes proven difficult under standard susceptibility testing conditions. In **heteroresistant** isolates, all cells in the population have the genetic element (*mecA* gene) for oxacillin resistance, but not all the cells express this resistance by virtue of PBP2a production. Consequently, in the oxacillin susceptibility test, some cells may appear resistant, and some can appear susceptible. If too few cells appear resistant, an oxacillin-resistant strain might not be detected. In addition, a rapid (5-minute) PBP2a colorimetric bench test, such as the Clearview PBP2a SA Culture Colony Test (Abbott Laboratories, Chicago, IL), may be performed on the isolate. However, this is not 100% reliable in detecting oxacillin resistance.

In vitro testing conditions can be modified to enhance the expression of oxacillin resistance, as follows:

- Preparation of inocula using the direct inoculum suspension procedure
- Incubation of tests at temperatures no higher than 35° C
- Making final test readings after a full 24 hours of incubation
- Supplementation of Mueller-Hinton broth or agar with 2% NaCl for dilution tests

The extended incubation allows the more slowly growing resistant subpopulation sufficient time to grow to detectable numbers. In addition, test plates should always be examined very closely. For oxacillin disk diffusion tests, zones of inhibition must be examined by using transmitted light (holding the plate up to the light source; see Fig. 13.11), and any growth is considered significant. A haze of growth within the inhibition zone for oxacillin-resistant isolates is sometimes observed (Fig. 13.13).

An **oxacillin-salt screen plate** that contains Mueller-Hinton agar supplemented with 4% NaCl and 6 μ g/mL oxacillin has been used to detect MRSA. The high salt concentration makes the medium selective for staphylococci. To perform the oxacillin screen test, a McFarland 0.5 suspension is prepared. A swab is dipped into this suspension and streaked over an area of approximately 2 $\times$ 5 cm or deposited as a spot on the agar surface. After overnight incubation at 35° C, growth (more than one colony) is an indication that the isolate is oxacillin resistant. This method does not reliably detect oxacillin-resistant, coagulase-negative staphylococci.

Testing a surrogate marker of resistance (i.e., cefoxitin) may provide a more accurate indication of oxacillin resistance

Fig. 13.13 The oxacillin zone for heteroresistant oxacillin-resistant *Staphylococcus aureus* often shows a haze of growth within the zone of inhibition. This haze is significant, and the isolate here is oxacillin resistant.

than testing oxacillin itself. This is because cefoxitin induces greater expression of PBP2a in *mecA*-containing strains of staphylococci and functions as a test agent to detect resistance. Studies have shown that performing a disk diffusion test with cefoxitin and using the specific cefoxitin breakpoints recommended by the CLSI provides sensitivity and specificity equivalent to testing oxacillin (by disk diffusion and MIC methods) with *S. aureus* and greater sensitivity and specificity of cefoxitin when testing coagulase-negative staphylococci. With *S. aureus*, cefoxitin disk diffusion test results are more easily interpreted than the results of disk diffusion tests using oxacillin. Thus cefoxitin disk diffusion testing is now recommended by the CLSI as the preferred method for detection of oxacillin resistance in *S. aureus* and coagulase-negative staphylococci. Even though it is coagulase-negative, *Staphylococcus lugdunensis* has characteristics that resemble those of *S. aureus*, and the results of the cefoxitin screen test should be interpreted using *S. aureus* interpretive criteria. It is important to report the findings from the cefoxitin disk diffusion test as indicative of oxacillin susceptibility or resistance; cefoxitin and cefazolin results should not be reported.

Case check 13.3

Just because a bacterium is susceptible in vitro to an antimicrobial, it does not mean that it can be used to treat an infection caused by the bacterium. In some cases, additional testing is required, as in the case of clindamycin-inducible resistance.

Sometimes, oxacillin-resistant staphylococci can appear susceptible in vitro to other β -lactam agents, such as the cephalosporins; however, these are clinically ineffective. Regardless of the in vitro test results, all oxacillin-resistant staphylococci must be reported as resistant to all β -lactam agents (including cephalosporins, β -lactam- β -lactamase inhibitor combinations, and carbapenems) if those agents are tested. For practicality, it is better simply to perform the cefoxitin disk diffusion test and deduce susceptibility to other β -lactam agents based on whether a staphylococcal isolate is oxacillin-susceptible or oxacillin-resistant. MRSA is a significant

cause of community-associated and healthcare-associated infections and requires that all clinical microbiology laboratories accurately detect drug resistance in *S. aureus*. Previously, healthcare-associated strains of MRSA were often resistant to several other drug classes in addition to the β -lactams. Although recent community-associated MRSA isolates often have been resistant only to the macrolides (e.g., erythromycin) in addition to various β -lactams, an increasing number of MRSA isolates from the community have the same antimicrobial resistance profile as healthcare-associated MRSA isolates.

Rare *S. aureus* isolates have a subtler and less common type of oxacillin resistance unrelated to the presence of the *mecA* or *mecC* genes. The resistance mechanism in these isolates is caused by hyperproduction of β -lactamase, or sometimes the presence of a point mutation in the gene coding for penicillin-binding protein but not PBP2a. These isolates generally have MICs just above (typically 1 to 8 $\mu\text{g}/\text{mL}$) or zones of inhibition just below the breakpoint for oxacillin susceptibility, and they are sometimes referred to as **borderline oxacillin-resistant *S. aureus*** (BORSA). Currently, the CLSI breakpoint for *S. aureus* $<2 \mu\text{g}/\text{mL}$ is sensitive and $>4 \mu\text{g}/\text{mL}$ is resistant; there is no intermediate result. Isolates with borderline oxacillin resistance generally do not grow on oxacillin screening plates. The clinical response of BORSA to penicillinase-resistant penicillins and to other β -lactam agents has not been clearly defined. The exact prevalence of BORSA strains is difficult to establish but is estimated to be 5% of *S. aureus* isolates. One study found that approximately 5% of asymptomatic children carried BORSA in the nares. Antimicrobial administration is likely the main risk factor for developing the BORSA phenotype.

Vancomycin resistance or diminished susceptibility in *Staphylococcus aureus*

Between 2002 and 2005, five different isolates of MRSA with vancomycin resistance were detected for the first time. These isolates had apparently either acquired a plasmid containing the *vanA* vancomycin resistance gene from **vancomycin-resistant enterococci** (VRE) or had developed mutations resulting in their cell walls being less susceptible to vancomycin. The MRSA isolates demonstrated various levels of resistance to vancomycin. Some were obviously resistant by routine susceptibility testing methods, and others were initially missed by routine testing methods. This important resistance followed recognition in 1996 of the first MRSA isolate, with subtle diminished susceptibility to vancomycin. Shortly thereafter, several similar isolates were encountered that all had vancomycin MICs of 8 $\mu\text{g}/\text{mL}$. Isolates of *S. aureus* with reduced susceptibility to vancomycin (MIC 4 to 8 $\mu\text{g}/\text{mL}$) are called **vancomycin-intermediate *Staphylococcus aureus*** (VISA). Resistance is not caused by the *vanA* gene but by changes in the cell wall, rendering them less susceptible to vancomycin. Although still uncommon, VISA and **vancomycin-resistant *Staphylococcus aureus*** (VRSA) isolates (as of 2019, only 14 strains of VRSA have been documented in the United States between 2002 and 2015) are of great concern because vancomycin is one of the most proven agents for treating serious MRSA infections. VRSA is defined as isolates with a vancomycin MIC $\geq 16 \mu\text{g}/\text{mL}$.

The CLSI recommends use of the broth microdilution test or vancomycin agar screen for enterococci as the best methods

for detection of VISA and VRSA. The **vancomycin agar screen plate** contains brain-heart infusion (BHI) agar supplemented with 6 µg/mL vancomycin and is useful in screening for vancomycin resistance in *S. aureus* and enterococci. The vancomycin disk diffusion test has not uniformly detected VISA and VRSA isolates, and some of the commercial susceptibility testing instruments have similarly not always provided reliable detection of these strains. In addition, heteroresistant vancomycin-intermediate *S. aureus* (hVISA) are isolates that normally test as susceptible by standard methods but contain a subpopulation of cells that test as nonsusceptible for vancomycin. The use of the macro Etest method, a modification of the standard Etest discussed later, has proven to be valuable in detecting hVISA. Because the test uses a higher concentration of bacteria (approximately 1×10^8 /mL) than that used routinely for susceptibility testing, the probability of detecting the small number of these organisms in the overall population of cells is enhanced. The Etest method can be used for detecting heteroresistance in other organisms to other antimicrobials.

Inducible clindamycin resistance in staphylococci

Two different mechanisms confer macrolide (e.g., erythromycin) resistance in staphylococci. The *erm* gene codes for methylation of the 23S ribosomal ribonucleic acid (rRNA), which results in resistance to erythromycin and inducible or constitutive resistance to clindamycin. The *msrA* gene codes for an efflux mechanism, which results in resistance to erythromycin but susceptibility to clindamycin. Consequently, when an erythromycin-resistant and clindamycin-susceptible staphylococcal isolate is encountered, a **D-zone test** for inducible clindamycin resistance must be performed before clindamycin is reported as susceptible. For the D-zone test, an erythromycin disk is placed adjacent to a clindamycin disk (15 to 26 mm, edge to edge) as part of a standard disk diffusion test. After overnight incubation, flattening of the clindamycin zone between the two disks (Fig. 13.14) indicates that the isolate has inducible clindamycin resistance because of *erm*. No flattening indicates that the isolate is erythromycin-resistant only (because of *msrA*). When an isolate demonstrates inducible resistance, clindamycin is reported as resistant. The phenomenon of clindamycin-inducible resistance also exists in *S. pyogenes* and *S. pneumoniae* and can be detected in a similar manner. Some automated susceptibility instruments can detect this inducible resistance.

Enterococci

The enterococci express low-level resistance to several antimicrobial agents including the aminoglycosides and β -lactams. In addition, they can also express high-level resistance to several agents. Penicillin resistance among the *Enterococcus* spp. is generally caused by overexpression of PBP with low affinity to the penicillins. Occasionally, *Enterococcus* isolates express a β -lactamase, notably *Enterococcus faecalis* and *Enterococcus faecium*. β -lactamases inactivate β -lactam molecules by disrupting the β -lactam ring component of the molecule (Fig. 13.15). Ampicillin or penicillin is normally effective in treating uncomplicated enterococcal infections (e.g., UTIs) by most *Enterococcus* spp. These cell wall active agents are only bacteriostatic against enterococci, and when administered alone are inadequate for treating serious infections, such as endocarditis, that require bactericidal therapy. To obtain a bactericidal effect, ampicillin or penicillin (or vancomycin in patients with penicillin allergies or with *E. faecium* infection) must be given in combination with an aminoglycoside, usually gentamicin or sometimes streptomycin.

Fig. 13.14 D-zone testing of *Staphylococcus aureus* that has *erm*-mediated inducible clindamycin resistance. The positive reaction is noted by a flattening of the zone around the clindamycin disk in the area in which there has been diffusion of erythromycin and clindamycin molecules overlap.

Fig. 13.15 β -Lactamase hydrolyzes the β -lactam ring portion of the penicillin molecule. The hydrolysis results in the formation of penicilloic acid, which does not have antibacterial activity.

Enterococci with the *blaZ* gene constitutively express β -lactamase at a much lower level than *S. aureus*, resulting in a clinically significant inoculum effect. Inoculating bacteria at concentrations for routine susceptibility testing (generally 1×10^5 organisms/mL), enterococci produce so little enzyme that they test susceptible to β -lactam agents. However, at a high inoculum, such as during an infection, the presence of more enzyme leads to resistance. Once the presence of a β -lactamase is identified, the addition of the β -lactamase inhibitor sulbactam (i.e., ampicillin-sulbactam) is sufficient to restore the antibiotic efficacy.

Detection of high-level aminoglycoside resistance in enterococci

Enterococci are inherently resistant to low concentrations of aminoglycosides, precluding their use as single agents for treatment of enterococcal infections. This low-level resistance is caused by poor drug uptake by enterococcal cells. For isolates with low-level aminoglycoside resistance, a synergistic interaction occurs when an aminoglycoside is administered together with a cell wall active agent such as ampicillin, penicillin, or vancomycin. Sometimes, however, enterococci develop **high-level aminoglycoside resistance** in which the aminoglycoside does not demonstrate synergism with the cell wall active agent. High-level aminoglycoside resistance in enterococci is usually caused by enzymatic inactivation of the drugs, and the enzymes that destroy gentamicin also destroy tobramycin, amikacin, and kanamycin (Table 13.5). Consequently, none of these agents is used in treating serious infections caused by enterococci with high-level gentamicin resistance. If the isolate does not have concomitant high-level streptomycin resistance, however, streptomycin could be used, although some isolates have high-level resistance to gentamicin and streptomycin.

In vitro tests for the detection of high-level aminoglycoside resistance include broth, agar, or disk diffusion methods. For screening, gentamicin is tested at concentrations of 500 μ g/mL and streptomycin at 2000 μ g/mL (agar) or 1000 μ g/mL (broth). The tests are performed as described for routine dilution tests, and growth at the high concentration indicates that the isolate has high-level resistance to the agent tested. Disk diffusion tests have also been described that use special potency disks containing high amounts of gentamicin (120 μ g) or streptomycin (300 μ g).

Table 13.5 Aminoglycosides represented when high concentrations of gentamicin and streptomycin are tested to determine high-level aminoglycoside resistance in enterococci	
Agent tested	Aminoglycoside(s) represented
Gentamicin ^a	Gentamicin
	Amikacin
	Kanamycin
	Tobramycin
Streptomycin ^b	Streptomycin
^a An isolate that has high-level resistance to gentamicin also has high-level resistance to the other aminoglycosides listed; enzymes that modify gentamicin also modify the other agents.	
^b An isolate that has high-level resistance to streptomycin has high-level resistance to this agent only, unless it also has high-level resistance to gentamicin as indicated by testing high concentrations of gentamicin.	

Detection of vancomycin resistance in enterococci

The incidence of vancomycin resistance in enterococci increased sharply in the 1990s and the early part of the first decade of this century. Among clinical isolates, *E. faecium* is the most common species demonstrating vancomycin resistance followed by *E. faecalis*. The most common mechanisms are the *vanA* and *vanB* genes, but other resistance genes have been described. Isolates that are highly resistant to vancomycin can be readily detected when tested by conventional antimicrobial susceptibility test methods. Some isolates, however, may have a more subtle type of vancomycin resistance, whereby MICs or inhibition zone measurements are just slightly above or below, respectively, the breakpoints. Hence dilution tests must be viewed closely, and inhibition zones in disk diffusion testing must be examined using transmitted (rather than reflected) light; any growth within the zone should be considered significant. Vancomycin screen agar can be used to detect vancomycin resistant enterococci as well.

Low-level vancomycin resistance is intrinsic in the motile enterococcal species *Enterococcus gallinarum* and *Enterococcus casseliflavus*. These differ from true VRE for infection control purposes. In addition, vancomycin-variable enterococci have been described. These isolates initially appear susceptible to vancomycin but possess the *vanA* gene (detected by molecular methods) and can develop into vancomycin-resistant strains *in vivo*; therefore they should be reported as vancomycin resistant. *Leuconostoc*, *Pediococcus*, and *Lactobacillus* spp. demonstrate intrinsic, high-level vancomycin resistance; these bacteria must be carefully separated from the morphologically similar enterococci and streptococci.

Extended-spectrum β -lactamases

Most *K. pneumoniae*, *Klebsiella oxytoca*, and many *E. coli* isolates are resistant to ampicillin because of the production of a plasmid-mediated β -lactamase: *TEM-1* or *SHV-1*. Most isolates are susceptible to later-generation cephalosporins and aztreonam; however, spontaneous mutations occur that can result in novel **β -lactamases** that can inactivate extended-spectrum cephalosporins, penicillins, and aztreonam. These β -lactamases are known as **extended-spectrum β -lactamases** (ESBLs). The enzymes are characterized and numbered based on their relationship to the parent enzymes. There are now more than 130 TEM-derived ESBLs and more than 60 derived from SHV-1. In addition, other novel β -lactamases have been designated as CTX-M or OXA that are not a result of mutations of the TEM or SHV parent enzymes. Some of these β -lactamases give rise to subtle or difficult to detect resistance among cephalosporins, penicillins, or aztreonam. Recently these enzymes have been found in other genera and species, including *Proteus mirabilis*, *Salmonella* spp., and *Enterobacter* spp. most notably.

Strategies for laboratory detection of ESBL-producing *E. coli*, *Klebsiella* spp., and *P. mirabilis* include testing of drugs that are most likely to indicate the presence of an ESBL (indicator drugs). These include, in decreasing order of sensitivity for detection, cefpodoxime, ceftazidime, cefotaxime, ceftriaxone, and aztreonam and the use of special screening zone or MIC breakpoints to facilitate recognition of ESBL production. Indicator drugs have been selected based on the likelihood of their being readily hydrolyzed by one of the many types of ESBLs. The use of more than one antimicrobial agent increases the sensitivity of detection.

Fig. 13.16 Extended spectrum β -lactamase (ESBL) phenotypic confirmatory testing of *Klebsiella pneumoniae*. The standard disk diffusion test is performed with cefotaxime and ceftazidime, with and without clavulanic acid. The diameter of the zone around cefotaxime–clavulanic acid (4-o'clock position) is more than 5 mm larger than the zone around cefotaxime (5-o'clock position), which indicates a positive reaction as clavulanic acid restores the activity of cefotaxime. Although the zones for ceftazidime and ceftazidime–clavulanic acid are comparable, only one set of drugs must be positive to confirm an isolate as an ESBL producer.

Once an ESBL-producing isolate is presumptively detected, confirmatory testing is optional per CLSI, because the breakpoints for the third- and fourth-generation cephalosporins have been lowered. ESBL activity is inhibited by β -lactamase inhibitor agents such as clavulanic acid; therefore this property forms the basis of the confirmatory tests. If the activity of cefotaxime, ceftazidime, or both is restored when tested in combination with clavulanic acid by disk diffusion or an MIC test, the resistance is caused by ESBL production. Fig. 13.16 shows an ESBL confirmatory test performed using the disk diffusion method.

Resistance in ESBL-producing strains to various β -lactam agents is not always predicted by in vitro tests performed using standard inoculum density. For example, a confirmed ESBL-producing *K. pneumoniae* isolate may appear susceptible to cefotaxime by a disk diffusion or MIC test; however, cefotaxime is hydrolyzed at a high inoculum density and is ineffective in treating infections caused by these strains. Consequently, when an ESBL-producing isolate is identified and confirmed, it should be reported as clinically resistant to all cephalosporins, penicillins, and aztreonam, despite the in vitro test results. The carbapenems (imipenem, meropenem, ertapenem) are active against ESBL-producing strains as are the cephamycins (cefoxitin and cefotetan). ESBL-producing isolates show variable susceptibility to aminoglycosides, fluoroquinolones, and trimethoprim-sulfamethoxazole, although many isolates show multiple drug resistance to those agents.

Carbapenemases

Carbapenemase-producing Enterobacterales (CPE) are increasingly seen in the clinical setting. These organisms carry resistance genes, often on plasmids, to carbapenem antibiotics as well as penicillins, monobactams, and cephalosporins to different degrees. It is vitally important to detect CPE for effective patient treatment and infection control purposes.

Klebsiella pneumoniae carbapenemase

K. pneumoniae carbapenemases (KPCs) are the most common type of CPE in the United States. Initially identified

in *K. pneumoniae*, they have been recognized in a variety of other members of the Enterobacterales, as well as some nonfermenters, such as *Pseudomonas aeruginosa*. Organisms possessing these enzymes are often resistant to one or more of the carbapenems. If an isolate possesses an ESBL and the MIC for a carbapenem is 2 or 4 $\mu\text{g/mL}$, there is a possibility that it may produce a KPC-type or some other carbapenemase.

Molecular methods can detect carbapenemase genes, but these tests are limited in terms of required expertise, time, and sample number. A simple, objective, inexpensive phenotypic method, the carbapenem inactivation assay, was endorsed by the CLSI in 2017. In this test, a carbapenem disk is incubated in water or trypticase soy broth (TSB) containing a suspension of a suspected carbapenemase-producing organism for 4 hours. Inactivation of the disk is analyzed by placing that carbapenem disk on a lawn plate of a carbapenem-susceptible control strain, resulting in no zone of inhibition after overnight incubation. Lateral flow assays, such as the NG-Test Carba 5 (Hardy Diagnostics, Santa Maria, CA), have been developed that will detect up to 5 different carbapenemases. In vitro susceptibility testing of members of the Enterobacterales containing KPCs may indicate that the isolate is susceptible to carbapenems, but therapeutically the carbapenem antimicrobial might not be effective. Infections often are treated with colistin or polymyxin with mixed results.

β -Lactamase tests

As mentioned previously, the β -lactamases inactivate some β -lactam antibiotics. Production of β -lactamase is a significant mechanism contributing to antimicrobial resistance in organisms, such as *Staphylococcus* spp., *H. influenzae*, *N. gonorrhoeae*, *M. catarrhalis*, several *Bacteroides* spp., and occasionally *Enterococcus* spp. and *Pseudomonas* spp. β -Lactamases are the primary mode of resistance to β -lactam antibiotics. Another method discussed earlier is altered PBPs with lower affinity to the β -lactams.

Several tests can be performed in the clinical laboratory to identify β -lactamase production, and the rapidity of β -lactamase tests makes them attractive as a means for direct detection of one important resistance determinant. A positive result means that the β -lactam agents commonly used (ampicillin, amoxicillin, and penicillin) to treat infections caused by the organism would be ineffective. Some β -lactams (e.g., oxacillin), however, are resistant to β -lactamase. A negative reaction indicates that the test organisms do not produce β -lactamase, although they may be resistant to these agents through another mechanism. Resistance related to other mechanisms can be detected only with conventional dilution or disk diffusion tests. Some organisms, such as members of the order Enterobacterales and the *Pseudomonas* spp., produce a variety of different types of β -lactamases; the currently available direct β -lactamase tests cannot reliably predict resistance to the newer β -lactam agents that might be used for these organisms, so β -lactamase testing should not be performed on them.

The most accurate means to determine β -lactamase production is by detecting the *blaZ* gene with real-time PCR. The most used direct detection method incorporates the chromogenic cephalosporin nitrocefin. Cefinase disks BD BBL (Thermo Fisher Scientific, Waltham, MA) are a commercial

product consisting of filter paper disks impregnated with nitrocefin approved for use on isolated colonies of *N. gonorrhoeae*, *Staphylococcus* spp., *H. influenzae*, enterococci, and anaerobic bacteria. A disk is moistened with water or saline, and a loopful of organisms is applied directly onto the disk. A β -lactamase-producing organism will turn red within 10 minutes (or within 60 minutes for staphylococci). No color change indicates a β -lactamase-negative organism (Fig. 13.17).

Other less commonly used β -lactamase tests utilize penicillin-based acidimetric and iodometric tests that detect the production of penicilloic acid from the hydrolysis of penicillin by a β -lactamase. The acidimetric method uses citrate-buffered penicillin and phenol red as a pH indicator. When β -lactamase-producing bacteria are added to the solution, the penicilloic acid results in a drop in pH, causing a color change from red to yellow. In the iodometric method, a solution of phosphate-buffered penicillin and starch-iodine complex is used. With β -lactamase-positive organisms, penicilloic acid reduces iodine and prevents it from combining with starch. A positive reaction is colorless, and a negative reaction is purple.

Most bacteria, except staphylococci, produce β -lactamase constitutively, meaning that the same amount of enzyme is produced regardless of exposure to an inducing agent. Production of β -lactamase in staphylococci is inducible, and exposure to an inducing β -lactam agent is often required to obtain a high enough concentration of the enzyme for detection with conventional β -lactamase tests. Studies have indicated that the nitrocefin test has low sensitivity for detecting β -lactamase activity in *S. aureus*. Testing organisms that were exposed to an inducing agent can be accomplished by using growth from the periphery of a zone surrounding a β -lactam disk. Taking the inoculum directly from the zone edge of a cefoxitin disk (30 μ g) from a standard disk diffusion test can increase the sensitivity. This is particularly true for the coagulase-negative *Staphylococcus* spp.

Studies showed that the penicillin disk zone edge test is the most sensitive method, and the CLSI recommends this test for determining β -lactamase production in *S. aureus*. For the CLSI protocol, a 10-unit penicillin disk is used in a standard disk diffusion test. The breakpoint for resistance is a zone <29 mm. Isolates with a sharp zone

edge are considered positive for β -lactamase production, while those with a feathered edge are regarded as negative. Reading the results is highly subjective; zones must be examined carefully with reflected light. The European Committee on Antimicrobial Susceptibility Testing recommends using a 1-unit penicillin disk and a breakpoint of <26 mm; studies indicate it to be more sensitive in detecting β -lactamase production in staphylococci. The CLSI does not recommend the zone edge test for coagulase-negative *Staphylococcus* spp.

Etest

The Etest uses the principle of an antimicrobial density gradient in agar medium as a means of determining antimicrobial susceptibility. The Etest uses thin plastic test strips impregnated on the undersurface with an antimicrobial concentration gradient and marked on the upper surface with a concentration index or scale. The strips may be placed in a radial fashion on the surface of an agar plate that has been inoculated in a manner like that for a disk diffusion test. After overnight incubation, the test results are read by viewing the plates from the top, with the lids removed. The antimicrobial gradient that forms in the agar around the Etest strips gives rise to an elliptic inhibitory area around each strip. The MIC is determined by where the growth ellipse intersects the Etest strip (Fig. 13.18). Like the disk diffusion test, the Etest has the flexibility of drug selection and testing because selected strips are applied to the surface of test plates. The cost of Etest strips is much more than that of antimicrobial disks, however, and is the main limitation of this product. Generally, published studies have indicated that MICs determined using the Etest compare favorably (within one twofold dilution interval) with those determined by conventional broth or agar dilution methods.

The Etest can be especially useful for testing fastidious organisms such as *S. pneumoniae*, other streptococci, *H. influenzae*, and anaerobic bacteria, in part because the strips can be placed on enriched media or in a special incubation atmosphere (e.g., increased CO₂ or anaerobic) and because relatively few antimicrobial agents may need to be tested against fastidious organisms. Consequently, the relatively high cost of the Etest strips could be minimized.

Fig. 13.17 Cefinase β -lactamase disk test. Cells from several colonies of *Haemophilus influenzae* were applied to a moistened disk. This photo shows results after testing of two different isolates. Within 10 minutes, the disk on the left turned brown-red (positive), and that on the right maintained a light yellow color (negative).

Fig. 13.18 *Escherichia coli* tested with an Etest gentamicin strip. The gentamicin minimal inhibitory concentration (where the ellipse crosses the gradient) is 0.75 μ g/mL.

Automated antimicrobial susceptibility test methods

Principles of technologies used

The automated susceptibility testing instruments currently available represent a choice of several different levels of automation. One instrument interprets growth end points of broth microdilution panels only when they are placed into an automated reader device, whereas other instruments provide hands-off incubation and reading functions for microdilution trays or special cards in an incubator-reader device. The instruments that offer the highest level of automation accomplish these tasks using robotics to move the panels or cards in the instrument during the incubation-reading sequences or to add reagents to certain test wells for biochemical tests.

Current instruments use one of two optical approaches for examining the test wells of the antimicrobial-containing panels or cards. Most instruments use the principle of turbidimetric detection of bacterial growth in a broth medium in test wells by a photometer. The determination of antimicrobial susceptibility is based on the lack of development of turbidity (growth suppression) or, conversely, an indication of resistance based on an increase in turbidity in the presence of an antimicrobial agent. The second means of recognizing growth is detecting hydrolysis of a fluorogenic growth substrate incorporated in a special test medium. With this method, growth is detected by a fluorometer as emission of a fluorescent signal when a microorganism consumes fluorophore-labeled substrate in the test medium during growth.

Instruments for antimicrobial susceptibility testing can provide test results after a conventional overnight incubation period or in a period of 5 to 15 hours. Instrumentation can interpret antimicrobial susceptibility test end points sooner than manual readings because of the greater sensitivity of the instruments' optical systems in detecting subtle increases in microbial growth. All of the instruments utilize computers to provide reports and to store and retrieve data on antimicrobial susceptibility. Most of the instruments can also be used to identify bacteria and to merge and print identification and antimicrobial susceptibility results into a single report and transfer the information to a laboratory information system (LIS).

Automated systems

Reader devices for broth microdilution susceptibility tests

Commercial manufacturers of broth microdilution antimicrobial susceptibility testing panels offer a view box or other device to facilitate the manual reading of results after incubation. They offer freeze-dried antimicrobial panels with a mechanized device to simplify hydration and inoculation of freeze-dried panels. Some manufacturers provide frozen panels. The Sensititre Vizion (Thermo Fisher Scientific) offers an instrument-assisted manual reader that allows the laboratory scientist to record the results using customizable lighting options to produce an easy-to-read digital plate image.

A similar instrument is the MicroScan TouchScan (Beckman Coulter Pasadena, CA). The MicroScan AutoSCAN-4 is a semi-automated system. After trays are incubated offline, the laboratory scientist inserts a tray into the reader that interprets growth patterns in panels by turbidimetric analysis.

Automated instrument systems

Currently, four instruments are available that can generate rapid (5 to 15 hours) or overnight (16 to 24 hours) susceptibility test results.

BD Phoenix system

The BD Phoenix automated microbiology system (BD Diagnostic Systems, Sparks, MD) is marketed in Europe, Japan, Canada, and the United States. The original Phoenix system consists of an instrument with a built-in keyboard and bar-coding station that can accommodate 100 test panels simultaneously, along with a separate printer (Fig. 13.19). The specially designed test cartridges contain 136 small wells (Fig. 13.20) to test as many as 25 different antimicrobial agents, alone or in combination with wells containing biochemical substrates for simultaneous identification of common gram-positive or gram-negative bacteria (combo panels). The test panels are inoculated manually by a simple, gravity-fed transfer of inoculated medium throughout the disposable cartridge after pouring inoculated broth through an opening in the test device. After inoculation, the panels are placed into the instrument's incubator. The Phoenix system

Fig. 13.19 BD Phoenix automated microbiology system. (Courtesy BD Diagnostic Systems, Sparks, MD.)

checks the panels for growth in the test wells every 20 minutes using a redox indicator system, resembling resazurin, and turbidity. The indicator is added to the broth at the time of organism inoculation. This approach allows susceptibility determinations after approximately 6 to 8 hours of incubation. The Phoenix instrument includes a rules-based expert system (BDXpert) and can be purchased with a data management personal computer and software package called *BD EpiCenter*, which allows networking with other BD microbiology instruments and a bidirectional interface for connection with an LIS.

MicroScan WalkAway system

The first MicroScan WalkAway system (Beckman Coulter) was developed in the 1980s. The current fourth-generation system, the WalkAway *plus*, consists of a self-contained incubator-reader unit with capacity for 40 or 96, 96-well panels, LabPro information management software, a printer, and an LIS interface (Fig. 13.21). The WalkAway uses microdilution panels that are hydrated and inoculated with a hand-operated inoculator device (MicroScan Renok, Siemens Healthcare Diagnostics, Tarrytown, NY; Fig. 13.22). Panels are

then placed in the incubator module. The type of test to be performed is indicated on an instrument-readable bar-code label located on the end of each panel. The instrument incubates the panels for the appropriate period (depending on the type of panel and organism), robotically positions the trays to add reagents for biochemical tests, and moves them under the photometer to perform growth readings.

Standard panels are read turbidimetrically after 16 to 18 hours of incubation with 24-hour holds for specific bacteria (e.g., oxacillin for *Staphylococcus* and vancomycin for *Enterococcus*). The instrument offers the possibility of early, read-when-ready interpretations of the standard panels in 4.5 to 6.5 hours if an isolate is unequivocally susceptible or highly resistant. Organisms with inducible or slow to be expressed resistance are automatically extended to 16- or 18-hour incubation. MIC or breakpoint panels are available for testing of gram-positive and gram-negative bacteria as are special combination panels that allow simultaneous susceptibility and organism identification in the same panel. With the standard panels, it is possible to read the panels visually in case of instrument malfunction. Panels containing lysed horse blood (MICroStrep, Beckman Coulter) are also provided for testing

Fig. 13.20 BD Phoenix test cartridges, which contain 136 wells of antimicrobial agents or biochemical tests.

Fig. 13.22 MicroScan Renok inoculator device, which is used to reconstitute and inoculate dried antimicrobial agents or biochemical tests in the test panels. A test panel is also shown. (Courtesy Siemens Healthcare Diagnostics, Tarrytown, NY.)

streptococci that can be read manually or by an automated system. The instrument includes a rules-based expert system (LabPro Alert_{EX}) and can be purchased with a software package called *LabPro* that allows networking with other MicroScan analyzers and workstations and a bidirectional interface with an LIS.

Sensititre ARIS 2X

The Sensititre ARIS 2X (Thermo Fisher Scientific) automated incubator reader was the first system to be marketed in the United States (in 1992) that used a fluorometric detection system for detecting growth end points of common, rapidly growing bacteria. It was found that the fluorogenic substrate system could not accurately detect some resistance mechanisms in 5 hours. Therefore the system has FDA approval for only 16- to 24-hour incubation for susceptibility testing.

The Sensititre ARIS 2X (Fig. 13.23) is a fully automated, benchtop incubating and reading system. The system utilizes up to 64, 96-well trays. The AutoReader uses an internal bar-code scanner to identify each plate type and assign the appropriate incubation time; when the assigned time has elapsed, the plate is then transported to the OptiReader for fluorescence measurement, with no manual intervention. Panels for *M. tuberculosis* are also available.

VITEK systems

The VITEK systems (bioMérieux) were originally designed for use in the U.S. space exploration efforts of the 1970s as an onboard test system for spacecraft exploring other planets for life. Because of its original design intention, it was highly automated and relatively compact. Small plastic reagent cards, similar in size to a credit card, contain microliter quantities of various concentrations of antimicrobial agents in 64 wells for susceptibility and identification testing. The VITEK 2 (Fig. 13.24) can accommodate up to 60 cards, while the VITEK 2XL holds up to 120 cards. The newest VITEK 2 Compact for small laboratories is available in three sizes: 15, 30, or 60 cards. The susceptibility cards allow quantitative MIC results accompanied by susceptible, intermediate, or resistant results interpretations for most rapidly growing, gram-positive and gram-negative aerobic bacteria in 4 to 18 hours. The VITEK 2 can test *S. pneumoniae* in addition to

the nonfastidious, aerobic gram-positive and gram-negative bacteria. The VITEK 2 offers one of the highest levels of automation currently available in microbiology instrumentation.

VITEK hardware consists of a filling module for inoculation of the cards, an incubator-reader module that incorporates a carousel to hold the test cards, a robotic system to manipulate the cards, a photometer for turbidimetric measurement of growth every 15 minutes, and a computer module with a video display terminal and printer for viewing and printing results. VITEK also offers a data management system (Observe) for storing and retrieving test data for a variety of epidemiologic reports.

The VITEK 2 Compact is a less automated version of the VITEK 2 that uses the same cards but without the smart carrier and programmed cassette for specimen handling automation available in the VITEK 2. It includes a compact, self-contained vacuum chamber and card sealer. The instrument is a less expensive option for laboratories that do not require the level of automation provided by the smart carrier of the VITEK 2. All VITEK instruments use kinetic measurements of growth in the presence of antimicrobial agents to provide analysis of growth curves, leading to computer algorithm-derived MICs. All instruments include a rules-based expert system, Advanced Expert System, to assist in controlling common technical errors and facilitate detection of unusual resistance mechanisms before results are reported.

Quality control of antimicrobial susceptibility tests

QC of antimicrobial susceptibility tests involves testing reference strains with defined antimicrobial susceptibility or resistance to the drugs tested. It is important to use QC strains that represent the types of patient isolates tested in the respective laboratory. Also, the QC strains should represent various degrees of susceptibility or resistance. Ideal QC strains for MIC tests have what are termed *on-scale MIC end points* for the drugs tested. An on-scale end point falls within the range of concentrations tested compared with off-scale end points, in which the MIC is less than the lowest or greater than the highest concentration tested.

The CLSI has identified American Type Culture Collection (ATCC) strains useful for QC testing (Table 13.6). The CLSI documents also include tables that define acceptable results

(zone measurements for disk diffusion tests) for these strains; examples are shown in Table 13.7. The procedure followed in testing QC reference strains must be identical to that used for testing patient isolates. If results with QC strains do not fall within the defined acceptable limits, corrective action must be taken to determine the reason for the out-of-control observation before reporting any patient results. QC testing is recommended each day that patient tests are performed; however, the frequency of QC testing can be reduced to weekly if a laboratory can demonstrate acceptable performance with the QC strains. This consists of obtaining results within acceptable limits for each antimicrobial agent–QC strain combination for 20 or 30 consecutive test days. QC procedures must be performed when new lots of materials are put into use, and test materials must never be used beyond their stated expiration dates.

Supplemental QC strains may be periodically tested to validate acceptable performance of specific antimicrobial agent–organism combinations that may be only modestly controlled with routine reference strains. For example, a

MRSA strain could be included to ensure that the test system can detect heteroresistant strains. Similarly, ampicillin-resistant *Enterobacter cloacae* might be included to ensure that the system can detect ampicillin resistance in gram-negative bacteria. Supplemental QC strains are sometimes used for troubleshooting specific problems or training new employees. Another component of a QC program involves the inclusion of mechanisms to ensure that those performing the testing are proficient in their tasks. Self-assessment checklists and supervisory reviews of reported results are examples of such mechanisms. Satisfactory performance on proficiency survey specimens and the use of relevant testing strategies are also QC parameters.

The most widely used supplemental QC measure is antibiograms to verify results generated on patient isolates. An **antibiogram** is the antimicrobial susceptibility profile of a bacterial isolate to a battery of antimicrobial agents. Some species have typical antibiograms, which can be used to verify the identification and susceptibility results on the isolate (Table 13.8). For example,

Table 13.7 Acceptable limits for quality control strains used to monitor accuracy of disk diffusion testing of nonfastidious organisms^a

Antimicrobial agent	Disk content (µg)	<i>Escherichia coli</i> ATCC 25922 (mm)	<i>Staphylococcus aureus</i> ATCC 25923 (mm)	<i>Pseudomonas aeruginosa</i> ATCC 27853 (mm)	<i>Escherichia coli</i> ATCC 35218 (mm)

Tobramycin	S	S	S	S	R
Trimethoprim-sulfamethoxazole	S	S	S	R	S

^aResults indicated represent the typical response found in most clinical isolates; however, these can vary significantly.

R, Resistant; S, susceptible; S-R, variable result.

P. aeruginosa is typically resistant to ampicillin, cefazolin and other first- and second-generation cephalosporins, and trimethoprim-sulfamethoxazole; however, it is often susceptible to gentamicin and other aminoglycosides, extended-spectrum penicillins (e.g., piperacillin), and ciprofloxacin. In contrast, *E. coli* is generally susceptible to all of the antimicrobial agents mentioned. Table 13.9 shows several atypical antibiograms suggesting that the result highlighted is erroneous. The CLSI provides a listing of results that should be verified because they (1) have never been encountered, (2) are uncommon, or (3) represent results that could easily occur because of technical errors and might have significant clinical consequences. One list includes susceptibility test results for certain genera or species that should be verified by all laboratories, and another includes results that need not be verified in facilities in which the results are common. Some of these listings are shown in Table 13.10.

When atypical antibiograms are seen, the results must be verified. Verification procedures include:

- Reexamination of the disk diffusion plate, MIC tray, and other components to ensure that results were properly interpreted and that the materials were not overtly defective (e.g., empty well in the tray)
- Checking earlier reports to see whether the particular patient previously had an isolate with an atypical antibiogram that was verified
- Repeating the test, if necessary. Sometimes it is necessary to repeat the identification and antimicrobial susceptibility tests to verify the atypical results; sometimes testing with an alternative method is useful.

With emerging resistance and healthcare-associated transmission of resistant organisms, there is now more variability in susceptibility profiles among clinical isolates than previously seen. In contrast with what was seen a decade ago, it would not be uncommon now for a facility to see a high percentage of isolates resistant to multiple antimicrobial agents.

Cumulative antibiograms are generated by the analysis of individual susceptibility results obtained on isolates from a

Table 13.9 “Problem” antibiograms suggestive of technical errors or patient issue

Antimicrobial agent	<i>Escherichia coli</i> ^a	<i>Enterobacter cloacae</i> ^b	<i>Pseudomonas aeruginosa</i> ^c	<i>Stenotrophomonas maltophilia</i> ^d
Amikacin	R	S	S	R
Ampicillin	S	R	S	R
Cefazolin	S	S	R	R
Cefoxitin	S	R	R	R
Cefotaxime	S	R	S-R	R
Gentamicin	S	S	S	R
Tobramycin	S	S	S	R
Trimethoprim-sulfamethoxazole	S	S	R	R

^aIt is very unusual for an isolate to be resistant to amikacin and susceptible to gentamicin and tobramycin because amikacin is typically the most active of these three aminoglycosides.

^bThird-generation cephalosporins (e.g., cefotaxime) are usually more active than second-generation cephalosporins (e.g., cefoxitin), which in turn are more active than first-generation cephalosporins (e.g., cefazolin) against the Enterobacterales. In addition, *E. cloacae* is typically resistant to cefazolin. Consequently, this antibiogram is unusual.

^cAmpicillin does not produce activity against *P. aeruginosa*, and this antibiogram is unusual.

^d*S. maltophilia* is usually susceptible to trimethoprim-sulfamethoxazole, which is the drug of choice for infections caused by this very resistant species. This antibiogram is unusual.

R, Resistant; S, susceptible; S-R, variable result.

Table 13.10 Suggestions for verification of antimicrobial susceptibility test results and confirmation of organism identification

Organism or group	Category I: verify at all laboratories	Category II: verify; institution specific
<i>Klebsiella</i> spp.	Ampicillin, S Automatically reported R regardless of result in some laboratories	ESBL confirmed positive Some instruments can reliably do this testing (i.e., Phoenix)
<i>Streptococcus pneumoniae</i>	Fluoroquinolone, R Linezolid, NS Vancomycin, NS	Penicillin, R Third-generation cephalosporin, R

ESBL, Extended-spectrum β -lactamase; NS, not susceptible; R, resistant; S, susceptible.

particular institution in a defined period; this represents the percentage of isolates of a given species susceptible to the antimicrobial agents commonly tested against that species (e.g., the percentage of *E. coli* isolates that are susceptible to ampicillin). Cumulative antibiograms are generally compiled annually to guide physicians in empiric therapy decisions. If a physician were treating a patient with a suspected infection caused by *P. aeruginosa* and the culture and susceptibility test results were not yet available, the physician could review the cumulative antibiogram to see the percentage of *P. aeruginosa* isolates in that facility susceptible to various antipseudomonal agents. This information could assist the physician in designing the empiric therapy regimen pending completion of culture and susceptibility testing. Cumulative antibiogram data also might be used for infection control purposes. An increase in the incidence of MRSA from 25% in the first quarter of the year to 60% in the second quarter might suggest a problem with healthcare-associated transmission of MRSA

among the patients in that facility. An investigation by infection control personnel into the reason behind such observations would be warranted.

Selecting an antimicrobial susceptibility test method

Clinical microbiology laboratories can choose from several manual or instrument-based methods to perform their routine antimicrobial susceptibility testing—the disk diffusion (or Kirby-Bauer) test, broth microdilution (with or without use of an instrument for panel readings), and rapid automated instrument methods. The Etest also can be useful for certain fastidious or obligate anaerobic bacteria.

The disk diffusion test provides the greatest flexibility and cost-effectiveness. A problem mentioned frequently with commercial microdilution or automated systems is the inflexibility of the standard antimicrobial agent batteries or test panels. With the current availability of more than 50 antimicrobial agents in the United States and the diversity among antimicrobial agent formularies in different hospitals, it is impossible for manufacturers to provide standard test panels that fit every hospital's needs. Thus the inherent flexibility of the disk diffusion test allows a laboratory to test any of 12 antimicrobial agents considered appropriate on a 150-mm Mueller-Hinton agar plate.

Other assets of the disk diffusion procedure are that it is one of the longest practiced standardized methods, and its performance is continually updated by the CLSI. The interpretive category results—nonsusceptible, susceptible, intermediate, resistant—of the disk diffusion test should be readily understandable by all physicians, which is frequently not the case with MIC results. Therefore it is useful to provide the interpretive category results along with the MIC.

As noted, commercial microdilution susceptibility test products are widespread in U.S. clinical laboratories.

Advantages of this method include its quantitative nature (an MIC rather than a category result), ability to determine MICs with some organisms for which the disk test may not be standardized, and the availability of automated panel readers. In addition, the computerized data management systems that accompany some of the instruments can be helpful to some laboratories for the storage and calculation of cumulative antibiograms and other susceptibility statistics.

A laboratory can perform automated antimicrobial susceptibility testing to reduce the amount of labor required for susceptibility tests and to generate test results more rapidly than can be accomplished by manual methods. Providing antimicrobial susceptibility tests a day or even hours sooner is a great advantage in patient care. Studies have documented a decrease in patient morbidity or mortality, as well as demonstrated substantial cost savings. If physicians are aware of critical susceptibility data on patients' isolates, an opportunity exists for improving the quality of care, quicker discharge of patients, or removal of patients from isolation or unnecessary and expensive empiric treatment (i.e., vancomycin), thus realizing cost savings.

Some time savings can be achieved with automated susceptibility instruments by using combination panels that allow antimicrobial susceptibility testing and organism identification on the same panel. In addition, some instruments provide mechanized or simplified panel inoculation and reading to achieve labor savings. The magnitude of the labor savings realized in clinical chemistry or hematology through automation has yet to be fully achieved in clinical microbiology. If a serious mechanical failure occurs, only tests from instruments that use conventional microdilution trays normally interpreted after overnight incubation can be completed by manual incubation and interpretation. The results obtained with instrument methods that incorporate rapid test interpretation or use fluorogenic substrate analysis cannot be manually interpreted. Therefore laboratories must have a backup testing procedure, such as disk diffusion or manual overnight broth microdilution testing, to avoid delays in generating patients' results.

A previous shortcoming of rapid susceptibility testing methods was the inability to detect certain inducible or otherwise subtle antimicrobial resistance mechanisms. Manufacturers have made significant strides toward solving these problems. In some cases, this has meant reformulating the test devices or improving the software used to interpret the susceptibility testing results, which can be aided in part by computer expert systems that detect common technical errors and explain some newer resistance mechanisms. Nevertheless, it is important for microbiologists to scrutinize carefully all susceptibility results before issuing final patient reports.

Rapid susceptibility determination

The successful treatment of infectious diseases requires not only the identification of the causative bacterium, but also determination of the bacterium's susceptibility to antimicrobials. Over the past several years, the rapid identification of bacteria has been more successful than the rapid determination of the bacterium's antimicrobial susceptibility. However, the detection of drug-resistant genes has demonstrated promise to increase the speed of determining a bacterium's resistance to antimicrobials. These rapid tests allow the treatment

of bacterial infections much sooner. Molecular methods for the detection of antimicrobial resistance genes are limited to those organism-antimicrobial combinations in which only a few genes are associated with the resistance, and the resistance has a high degree of clinical significance.

Currently, about eight systems have received FDA approval for nucleic acid amplification testing. They are based on two methodologies—PCR and solid-phase microarrays—and can be performed directly on clinical specimens or culture isolates. For example, the Verigene BC-GP (Luminex Corporation, Austin, TX) can identify several species of gram-positive bacteria and detect *mecA* resistance gene in *S. aureus* and *Staphylococcus epidermidis* and *vanA/B* genes in *E. faecalis* and *E. faecium* in a few hours directly from positive blood culture bottles. This assay is based on hybridization of DNA target sequences to nanoparticles and is classified as moderate complexity by CLIA. The BioFire FilmArray (bioMérieux) and GeneXpert (Cepheid, Sunnyvale, CA) are PCR-based instruments also classified as moderate complexity. Other systems are classified as high complexity. ESBL production by gram-negative bacteria is one of the greatest threats to antimicrobial therapy today. Several commercial assays for the molecular detection of ESBL exist. Some, like the FilmArray, have a single target (KPC), while others detect a variety of β -lactamases (e.g., Verigene). Probes directed toward genes responsible for other resistance mechanisms (e.g., aminoglycoside-modifying enzymes and tetracycline resistance factors) have also been described.

Special antimicrobial susceptibility tests

Clinical microbiology laboratories that perform bacterial cultures generally perform antimicrobial susceptibility tests by a disk diffusion or MIC method. These tests assess the ability of antimicrobial agents to inhibit the growth of bacteria and are sufficient for guiding antimicrobial therapy in most situations. In select cases, a physician may wish to determine how well specific antimicrobial agents kill bacteria or how the activity of a combination of antimicrobial agents compares with that of a single agent. Unlike disk diffusion and MIC tests, however, tests for bactericidal activity (e.g., MBC tests and **serum bactericidal tests** [SBTs]) and for antimicrobial synergism are not highly standardized. When patients are prescribed antimicrobial agents that have a low toxic-to-therapeutic ratio, it may be necessary to monitor the concentrations of drug in the patient's serum to avoid excessive concentrations that can be harmful. Various methods are used for these assays. Some antimicrobial susceptibility tests are generally performed only in specialized laboratories and are used in only a few defined clinical settings or for research purposes (Table 13.11).

Case in point

Viridans group *Streptococcus* was isolated from all six blood culture bottles submitted from a patient with suspected bacterial endocarditis. The isolate was susceptible to penicillin (MIC $\leq 0.03 \mu\text{g/mL}$), but the physician was concerned about the bactericidal activity of penicillin alone. The laboratory performed MBC testing and reported an MBC of $32 \mu\text{g/mL}$. The physician considered this

information in conjunction with clinical observations of the patient and documentation in the literature of previous experiences with patients with similar conditions. This patient continued with a therapeutic regimen of penicillin and gentamicin.

Issues to consider

After reading the patient’s case history, consider:

- Circumstances when it might be appropriate to do more than a disk diffusion or MIC test on a clinical isolate
- Factors that might contribute to the MBC being five twofold dilutions greater than the MIC
- Rationale for adding a second agent (gentamicin) to treat the infection

Minimum bactericidal concentration test

MIC tests identify the amount of antimicrobial agent required to inhibit the growth or multiplication of a bacterial isolate. If a concentration of antimicrobial agent that is the same as or preferably exceeds the MIC is attained at the infection site for an appropriate length of time, the drug generally inhibits multiplication of the bacteria such that the patient’s immune defense mechanisms can successfully eliminate the infecting bacteria. The immune defense mechanisms (e.g., phagocytic cells, antibody) work together with antimicrobial agents to eradicate infecting bacteria. For this reason, inhibitory concentrations of the drug at the infection site are generally sufficient for treating most infections.

In immunosuppressed patients and patients with serious infections such as endocarditis, meningitis, and osteomyelitis, immune defense mechanisms are suboptimal. Inhibitory concentrations of the drug may not be sufficient, and obtaining bactericidal concentrations of antimicrobial agents at the

infection site is important for achieving a cure. For many types of infections, the bactericidal capacity of a specific antimicrobial regimen can be predicted based on previous experience. For example, most β -lactam antimicrobial agents are bactericidal for *E. coli*, provided their MIC is in the susceptible range. On the other hand, the bactericidal activity of β -lactams and other cell wall-active agents (e.g., vancomycin) against *S. aureus* is less predictable. In circumstances in which a serious *S. aureus* infection occurs in a patient with poor immune defense mechanisms, an in vitro determination of the amount of antimicrobial agent required to kill the isolate may be helpful. The MBC test is used for this purpose. The MBC is defined as the lowest concentration of antimicrobial agent that kills 99.9% of the test bacteria. The CLSI has described procedures for assessing bactericidal activity; however, unlike disk diffusion and MIC tests, a standardized MBC test has not been in use for a sustained period. In the past, numerous procedural variations compromised the use of the test results.

The MBC test is performed in conjunction with a broth macrodilution or broth microdilution MIC test. The antimicrobial agent concentrations that show inhibition (equal to or greater than the MIC) may or may not have killed the bacteria in the test inoculum (Fig. 13.25). After the MIC determination, a 0.01-mL aliquot from each clear tube or well is subcultured onto an agar medium to determine the MBC. The numbers of colonies that grow on subculture are compared with the actual number of organisms inoculated into the MIC test tubes or wells to determine the extent of bactericidal activity at each antimicrobial concentration. If the numbers of colonies on a subculture plate total less than 0.1% of the initial inoculum (indicating 99.9% or more killing), by definition, a bactericidal effect has been achieved.

The number of bacteria in each tube (or well) immediately after inoculation of the MIC test tube or well is approximately

Table 13.11 Special antimicrobial susceptibility tests	
Test	Purpose
Antimicrobial concentration test (assay)	Measure of amount of antimicrobial agent in serum or body fluid
Minimum bactericidal concentration test	Measure of lowest concentration of antimicrobial agent that kills 99.9% of a bacterial isolate population
Serum bactericidal test	Measure of highest dilution or titer of a patient’s serum that is inhibitory to the patient’s own infecting bacterium and highest dilution or titer that is bactericidal
Synergy test	Measure of susceptibility of a bacterial isolate to a combination of two or more antimicrobial agents
Time-kill assay	Measure of rate of killing of bacteria by an antimicrobial agent (as determined by examining the number of viable bacteria remaining at various intervals after exposure to the agent)

Fig. 13.25 Broth macrodilution test showing vancomycin and *Staphylococcus aureus*. The minimal inhibitory concentration (MIC) is 1.0 $\mu\text{g/mL}$. The purity plate shows a pure culture. The colony count plate shows 53 colonies, which means that 5.3×10^5 colony-forming units (CFU) per milliliter were in the test tubes immediately after inoculation of the MIC test tubes. For the colony count plate, immediately after inoculation, the growth control tube was diluted 1:1000, and 0.1 mL was plated. Now 0.01 mL will be plated from each clear tube (tubes containing 1.0–128 $\mu\text{g/mL}$ vancomycin) for the minimum bactericidal concentration determination. Because it was shown that the actual colony count in the MIC test was 5.3×10^5 CFU/mL, growth of five or fewer colonies would indicate a 3 $\log_{10}$ decrease, or 99.9% killing. By definition, the concentration of drug in the respective tube would be considered bactericidal.

5×10^5 CFU/mL. For the MBC test, however, an actual colony count must be performed on the test inoculum when the MIC test tube or well is inoculated. A small aliquot from the growth control tube or well is diluted in saline or broth to obtain a countable number of colonies; the final dilution is plated on an agar medium. Generally, a 1:1000 dilution is performed (0.01 mL from the growth control tube is diluted in 10 mL), and 0.1 mL is spread over the surface of an agar plate, resulting in an overall dilution of 1:10,000. After overnight incubation, the number of colonies that grew on the colony count plate are counted. Because this count represents a 1:10,000 dilution, the count is multiplied by 10^4 to determine the number of bacteria in the original growth control and the antimicrobial agent solutions. The number of colonies representing a 99.9% reduction in the original inoculum is determined. This is the MBC end point.

In the example shown in Fig. 13.25, the actual count on the colony count plate is 53; therefore the number of bacteria in each tube of the MIC test immediately after inoculation was 5.3×10^5 CFU/mL (53 times the dilution factor 10^4). A 99.9% killing (or 0.1% survival) would be accomplished if five or fewer colonies grow on subculture of each clear well or tube after reading of the MIC test (Fig. 13.26). In this example, subcultures from all tubes containing 2.0 µg/mL vancomycin or more grew fewer than five colonies. Consequently, the MBC is 2.0 µg/mL. The 99.9% end point (or 3 log₁₀ reduction in growth of the original inoculum) is an arbitrary value, with 95% confidence limits, although its clinical relevance has not been rigorously confirmed. Measurement of MBC is thus a rough prediction of bacterial elimination and can be used for research purposes to evaluate new antimicrobial drugs.

Case check 13.4

The MIC of an antimicrobial agent determines the concentration required to inhibit the growth of a bacterium. This inhibition can be bacteriostatic or bactericidal. The concentration that must be achieved in certain clinical situations (e.g., endocarditis, meningitis) must be bactericidal to affect a successful outcome for the patient. In this case, an MBC test could improve patient outcomes.

Fig. 13.26 Subculture plates from the minimal inhibitory concentration test of vancomycin and *Staphylococcus aureus* shown in Fig. 13.25. Subcultures from tubes containing 8.0 to 128 µg/mL vancomycin show no growth. Subcultures from the tubes containing 2.0 and 4.0 µg/mL show one and two colonies, respectively, indicating a greater than 99.9% killing. More than five colonies have grown from the 1.0 µg/mL tube, so the minimum bactericidal concentration is 2.0 µg/mL.

Controlling test variables

MBC tests are subject to more technical pitfalls than MIC tests, and several variables must be rigidly controlled during MBC testing. The first involves inoculum. Because many antimicrobial agents exert a bactericidal effect only on growing cells, bacteria in the midlogarithmic phase of growth must be used as the inoculum to prevent falsely elevated MBCs. The inoculum preparation methods described for MIC tests that use stationary phase growth are unacceptable for MBC tests.

Second, during inoculation for MIC tests, care must be taken to ensure that all bacteria in the test inoculum are deposited directly into the antimicrobial solution. If this is not done, bacteria may stick to the wall of the tube or well above the meniscus of the antimicrobial solution and can remain viable during incubation of the MIC portion of the test. These cells (which have not been exposed to antimicrobial agent) might then be inadvertently transferred during the subculture step, ultimately resulting in falsely elevated MBCs.

Third, the volume subcultured after reading of the MIC test must be large enough to contain sufficient inoculum but small enough to prevent carryover of large amounts of antimicrobial agent that can continue to exert an antibacterial effect. Usually, 10 µL (0.01 mL) is recommended.

Interpretation concerns

Several interpretive problems, most common with β-lactam agents, have been associated with MBC tests, and they relate to technical or biological issues. Sometimes more colonies are growing on subcultures at higher drug concentrations than at lower concentrations. This decreased bactericidal activity at higher concentrations is referred to as a *paradoxical (Eagle) effect*. Sometimes small numbers, but slightly greater than 0.1% of the test inoculum, of bacteria grow on several subculture plates. This may occur if some bacteria are metabolically inactive or dormant (**persister cells**) at the times of testing. However, when the persisting colonies are retested, their MICs are comparable with those originally obtained. Finally, tolerance to the intrinsic bactericidal effect of an antimicrobial agent is demonstrated when the number of colonies growing on subculture plates exceeds the 0.1% cutoff for several successive drug concentrations above the MIC. **Tolerance** is generally defined as an MBC/MIC ratio of 32 or higher. Tolerance has been associated with a defect in bacterial cellular autolytic enzymes.

Time-kill assays

Bactericidal activity of antimicrobial agents also can be assessed by performance of in vitro **time-kill assays**. These assays examine the dynamics of synergism or antagonism of antimicrobial agents in combination, by determining the number of viable bacteria that remain over time after exposure to each individual drug and drug combinations. Because they are labor intensive, these assays are rarely performed in the clinical microbiology laboratory. They are performed rarely in the case of patients with meningitis or endocarditis with treatment failure and in research to study novel antimicrobial drugs. CLSI does not have a standardized procedure for these assays.

Case check 13.5

In some cases, a combination of antimicrobial agents (combination therapy) is required to effect killing of the bacterium to result in treatment success. An example is the use of a β -lactam drug and an aminoglycoside to treat serious enterococcal infections. A synergy test can be performed in the laboratory to confirm that this therapy would be effective.

Synergy tests

Some types of infections require therapy with a combination of two or more antimicrobial agents. Enterococcal endocarditis, for example, requires use of a penicillin (or vancomycin) and an aminoglycoside for reliable killing of the organism. A broad-spectrum cephalosporin and aminoglycoside are often prescribed for gram-negative sepsis in neutropenic patients. The goals of combination therapy are to obtain broad-spectrum coverage, enhance antibacterial activity through synergistic interactions, and minimize drug resistance development. For most infections requiring combination therapy, single-agent MIC results and previous experience in treating similar types of infections are sufficient to guide the proper selection of an antimicrobial agent.

Synergy tests are not routinely performed in the clinical laboratory but may be useful when a patient is not responding to what would appear to be an adequate regimen, unusual organisms or resistance properties are encountered, or host factors preclude the use of certain agents. Synergy testing for multidrug-resistant gram-negative bacilli and extremely drug-resistant mycobacteria is currently under study.

In vitro synergy tests may be performed using a broth microdilution checkerboard assay or broth macrodilution method, as described by CLSI. The checkerboard assay is a type of two-dimensional test. All steps are performed as for single agents, but two agents are tested in each well or tube. Checkerboard synergy tests are usually performed in broth microdilution MIC trays. A wide variety of combinations of concentrations are tested by dispensing drugs in a two-dimensional checkerboard format, and each drug tested in the combination is also tested alone. A combination is said to show **synergism** if its antibacterial activity is significantly greater than that of a single agent; that is, when the MIC for each drug in the combination is less than or equal to 25% of the single-agent MIC. Conversely, **antagonism** is defined as the activity of the combination less than (and MICs are greater than) that of the single agents. For **indifference**, the activity of the combination is equal to that of the single agents (Fig. 13.27).

Case check 13.6

Determining that the concentration of an antimicrobial agent in the blood (serum, plasma) is sufficient to kill the bacterium causing the infection is sometimes needed to confirm that the dosing of the agent is therapeutic.

Serum bactericidal test

In the late 1940s, Schlichter and MacLean described a test that measured the effectiveness with which penicillin in serum killed bacteria associated with subacute bacterial endocarditis (SBE). This test was subsequently referred to as the serum bactericidal test (SBT). There is no single standardized SBT method, though the CLSI has described methods in an approved guideline, including broth macrodilution and broth microdilution methods.

The SBT is like the MIC-MBC test in that the serum inhibitory test (SIT) and SBT parameters are evaluated. The patient's serum during drug therapy and the bacterial isolate responsible for the patient's infection are required. Serial two-fold dilutions of the patient's serum are prepared, and then a standardized inoculum of the patient's bacterial isolate is added to each dilution. After overnight incubation, the tubes or wells are examined to determine the greatest dilution of the patient's serum that inhibits the bacteria (SIT). Subsequently, as with the MBC test, the contents of all tubes or wells showing inhibition are subcultured on an agar medium to determine the highest dilution that kills >99.9% of the bacteria (SBT). The SBT result relates to the amount of antimicrobial agent and other antibacterial factors (e.g., antibody, complement) present in the patient's serum.

Timing the collection of serum is critical, and generally trough (taken just before drug is administered) and peak (taken soon after dose is administered) titers are tested. A trough bactericidal titer of 1:32 or greater and a peak bactericidal titer of 1:64 or greater has been historically correlated with bacteriologic cure in patients with endocarditis. The described methods are controversial, and currently there are few situations in which this test is of clinical value. Current drugs used for the treatment of SBE generally achieve bactericidal levels when given for therapy, and it is very difficult to achieve and monitor serum levels of the drug in the patient accurately.

Measurement of antimicrobial agents in serum and body fluids

The amount of antimicrobial agent in serum or other body fluid can be measured by a variety of antimicrobial assay procedures. Antimicrobial assays are performed for antimicrobial agents in which the therapeutic concentration is close to the toxic concentration. Assay results often lead to modification of subsequent doses to prevent accumulation of excessive drug concentrations that might be harmful to the patient. A patient's renal status and hepatic status greatly influence in vivo levels of some antimicrobial agents. The antimicrobial agents with the greatest toxic risks and those most commonly monitored are the aminoglycosides, vancomycin, and chloramphenicol. For evaluation of antimicrobial levels, trough and peak samples should be assayed as for the SBT.

Biological assays

Antimicrobial assays were initially performed by a biological assay (bioassay) method; bioassays are still sometimes used

Fig. 13.27 Assessment of antimicrobial combinations with the checkerboard method. All three diagrams depict the results of testing combinations of two drugs (diluted in geometric twofold increments along the x- and y-axes, drug A along the x-axis and drug B along the y-axis). Shading indicates visible growth, and concentrations are expressed as multiples of the minimal inhibitory concentration. **A**, Indifference. **B**, Synergism. **C**, Antagonism. (Modified from Pillai, S. K., et al. (2005). *Antimicrobial combinations*. In V. Lorian (Ed.), *Antibiotics in laboratory medicine: making a difference* (5th ed.). Philadelphia: Lippincott Williams & Wilkins.)

today when the focus is on the amount of biologically active drug present, rather than the amount of “chemical” present. The bioassays use a specific strain of bacteria (indicator organism) that is susceptible to the drug to be assayed. The test can be performed in broth or on agar. The antibacterial activity of the patient’s specimen against the bacterium is compared with that of solutions containing defined concentrations of the antimicrobial being assayed to determine the concentration in the patient’s specimen using standard dose-response curves.

Immunoassays

Radioimmunoassay, fluorescent immunoassay, fluorescent polarization immunoassay, and enzyme immunoassay procedures have all been used to measure antimicrobial agents in serum and other body fluids. The basic principles of these assays are similar in that they all use antibodies directed against the specific antimicrobial agents to be assayed. Because of the nature of these tests, they may be performed in the chemistry or immunology sections of the laboratory. Several commercial manufacturers offer various immunoassay kits for quantifying gentamicin, tobramycin, amikacin, vancomycin, and chloramphenicol assays.

Chromatographic assays

Various chromatographic methods, including gas-liquid, thin-layer, paper chromatography, and high-performance liquid chromatography, have been used on occasion for antimicrobial assays, primarily to measure levels of antimicrobial agents for which commercial immunoassay kits are not available. These tests are performed in research settings only.

POINTS TO REMEMBER

- Antimicrobial susceptibility testing is performed only on bacteria likely causing an infection.
- The CLSI determines standards for antimicrobial susceptibility testing and reporting in clinical laboratories in the United States.
- The FDA has the regulatory authority for setting susceptibility test interpretive criteria and QC parameters.
- Antimicrobial susceptibility testing protocols describing what, when, and how to test and report should be developed with input from clinicians, pharmacists, and others who have

clinical experience with the antimicrobial therapy practices of the institution.

- Selective or cascading reporting refers to reporting broader-spectrum agents only in select situations, such as when the patient's isolate is resistant to narrower-spectrum agents.
- Several variables must be controlled when performing any type of antimicrobial susceptibility test; inoculum standardization is one of the most important of these. Testing too few or too many bacteria can yield erroneous results.
- The disk diffusion, Etest, broth microdilution MIC test, and automated MIC tests are the most common methods currently used for antimicrobial susceptibility testing in clinical laboratories.
- The disk diffusion (or Kirby-Bauer) test is a qualitative method; results are reported as susceptible, intermediate, nonsusceptible, or resistant.
- The MIC test is a semi-quantitative method, and the concentration ($\mu\text{g}/\text{mL}$) of a drug required to inhibit the growth of bacterial isolate is reported together with a *susceptible*, *intermediate*, *nonsusceptible*, or *resistant* interpretation (e.g., ampicillin MIC = $8\mu\text{g}/\text{mL}$; susceptible).
- Routine antimicrobial susceptibility test methods can be modified for testing fastidious bacteria that require supplemental nutrients, modified incubation conditions, or both.
- An oxacillin disk ($1\mu\text{g}$) can be used to screen for penicillin susceptibility in *S. pneumoniae* on isolates not recovered from blood or CSF.
- β -hemolytic streptococci remain universally susceptible to penicillin, the drug of choice for treating infections caused by these organisms, and susceptibility testing is usually not required.
- The CLSI reference method described for testing obligate anaerobic bacteria is agar dilution; however, a broth microdilution method can be used for less fastidious species of anaerobes, such as *Bacteroides* spp.
- The gene most responsible for oxacillin resistance in staphylococci is *mecA*.
- The cefoxitin disk performs better than the oxacillin disk in detecting oxacillin-resistant staphylococci by the disk diffusion method.
- Oxacillin-resistant staphylococci should be considered resistant to all β -lactam agents (including cephalosporins, β -lactam- β -lactamase inhibitor combinations, and carbapenems), despite any susceptible result for these in vitro.
- The D-zone test uses erythromycin to detect inducible clindamycin resistance in staphylococci and β -hemolytic streptococci.
- The vancomycin broth microdilution MIC test or vancomycin agar screen is recommended to detect VISA or VRSA.
- VRE are important healthcare-associated pathogens; however, low-level vancomycin resistance is intrinsic in *E. gallinarum* and *E. casseliflavus*. These differ from true VRE for infection control purposes.
- ESBL-producing bacteria should be considered resistant to all cephalosporins, penicillins, and aztreonam, despite a susceptible result for these in vitro. ESBLs are prevalent in bacteria belonging to the order Enterobacterales.
- Most automated instruments for antimicrobial susceptibility testing are based on turbidimetric detection of bacterial growth or detection of hydrolysis of a fluorogenic growth substrate.
- QC of antimicrobial susceptibility tests is performed with standard reference strains that have defined antimicrobial susceptibility or resistance to the drugs tested.
- Certain species have typical antibiograms that can be used in empiric therapy and to verify the identification and susceptibility results generated on the isolate.
- Cumulative antibiograms represent the percentage of isolates of a given species susceptible to the antimicrobial agents commonly tested against the species.
- Nonsusceptible does not necessarily mean that the organism is resistant to the antimicrobial.
- MBC testing or serum bactericidal testing may be useful in select situations, such as for patients who are immunosuppressed with serious infections or in whom infection is at a site where immune mechanisms are not optimal, e.g., endocarditis.
- MBC testing is performed after completion of a broth dilution MIC test, and the end point is 99.9% killing of the test bacteria.
- Serum bactericidal testing requires use of the patient's serum obtained at appropriate times surrounding dosing of the antimicrobial agent(s), that is, peak and trough, and the bacterium causing the patient's infection.
- Synergism testing of drug combinations can be performed using a time-kill or checkerboard assay described by the CLSI in certain select situations.
- Many clinical laboratories use a *mecA* assay to determine oxacillin susceptibility or resistance in staphylococci and *vanA* and *vanB* assays to detect vancomycin resistance in enterococci.

LEARNING ASSESSMENT QUESTIONS

1. Why would it be inappropriate to perform antimicrobial susceptibility tests on viridans streptococci isolated from a throat culture?
2. The turbidity of a McFarland 0.5 standard corresponds to approximately ____ colony-forming units per milliliter.
3. The ____ disk cannot be used to screen for penicillin susceptibility in *Streptococcus pneumoniae* from sputum.
4. Which method does the Clinical and Laboratory Standards Institute (CLSI) suggest as the most reliable for detecting oxacillin resistance in staphylococci?
 - a. Oxacillin disk diffusion test
 - b. Cefoxitin disk diffusion test
 - c. Penicillin minimal inhibitory concentration (MIC) test
 - d. Oxacillin agar screen
5. What does the *mecA* gene code for in staphylococci?
 - a. β -Lactamase and penicillin resistance
 - b. Altered penicillin-binding protein and vancomycin resistance
 - c. Penicillin-binding protein 2a and oxacillin resistance
 - d. β -Lactamase and oxacillin resistance
6. With which of the following profiles should *S. aureus* or β -hemolytic streptococci be subjected to in D-zone testing?
 - a. Oxacillin-resistant
 - b. Penicillin-resistant
 - c. Erythromycin-resistant and clindamycin-resistant
 - d. Erythromycin-resistant and clindamycin-susceptible
7. An ampicillin-susceptible *Enterococcus faecalis* from a blood culture has high-level resistance to the aminoglycoside gentamicin. Which of the following statements is true?
 - a. Ampicillin and gentamicin will be synergistic.
 - b. Ampicillin and gentamicin will not be synergistic.

- c. Penicillin and gentamicin will be synergistic.
- d. Cefazolin and gentamicin will be synergistic.
8. Extended-spectrum β -lactamase-producing isolates should be considered resistant to which of the following agents?
 - a. Cephalosporins, penicillins, and aztreonam
 - b. Cephalosporins, penicillins, and aminoglycosides
 - c. Cephalosporins, penicillins, and β -lactamase inhibitors
 - d. Cefotaxime-clavulanic acid and ceftazidime-clavulanic acid
9. Which of the following organisms is commonly tested for β -lactamase production?
 - a. *Neisseria meningitidis*
 - b. *Klebsiella pneumoniae*
 - c. *Streptococcus pneumoniae*
 - d. *Haemophilus influenzae*
10. Which of the following statements is true about quality control (QC) testing of antimicrobial susceptibility tests?
 - a. A laboratory must perform QC every day that patient isolates are tested.
 - b. A laboratory can perform QC weekly if it performs fewer than 10 tests daily.
 - c. A laboratory can perform QC weekly once accurate performance of 20 to 30 days of daily QC has been documented.
 - d. A laboratory does not have to perform QC if an automated test antimicrobial susceptibility test system is used.
11. Identify each of the following statements as true or false.
 - a. Ampicillin susceptibility in *Pseudomonas aeruginosa* is unusual. ____
 - b. Many *Staphylococcus aureus* strains are vancomycin resistant. ____
 - c. Penicillin is the drug of choice for treating gonorrhea. ____
 - d. *Stenotrophomonas maltophilia* strains are usually susceptible to trimethoprim-sulfamethoxazole. ____
 - e. *Escherichia coli* strains are expected to be resistant to all aminoglycosides. ____
12. Which of the following statements is true?
 - a. An organism that is reported as nonsusceptible to an antimicrobial is definitely resistant to the antimicrobial.
 - b. The term nonsusceptible is used when the interpretive categories of intermediate and resistant do not apply.
 - c. The organization that oversees preparing technical documents for international use is the European Medicines Agency.
 - d. The *vanA* gene codes for chloramphenicol resistance.
13. Why is a bactericidal drug regimen necessary for treating patients with bacterial endocarditis?
14. The MBC end point is the lowest concentration of antimicrobial agent that kills --- of the test bacteria.
15. It is important to test bacteria in the --- phase of growth when performing tests to assess bactericidal activity.
16. Which of the following definitions best describes synergism?
 - a. The activity of the drug combination is greater than that of the individual agents.
 - b. The activity of the drug combination is less than that of the individual agents.
 - c. The activity of the drug combination is equal to that of the individual agents.
 - d. The test organism is resistant to both drugs in the combination.
17. Why is the use of molecular assays to detect antimicrobial resistance genes limited?
 - a. Genes are not responsible for most types of antimicrobial resistance.
 - b. Genes may be present but may not be expressed; therefore the presence of the gene does not always correlate with resistance.
 - c. Researchers have been unable to identify genes for antimicrobial resistance.
 - d. Testing is too expensive.
18. Which of the following classes of antimicrobial agents poses the greatest toxicity risks and therefore is frequently monitored using antimicrobial assays?
 - a. Cephalosporins
 - b. Sulfonamides
 - c. Aminoglycosides
 - d. Tetracyclines
19. The presence of the *blaZ* gene is expected to confer resistance to which of the following?
 - a. Cephalosporins only
 - b. Erythromycin
 - c. Oxacillin
 - d. Several β -lactam antibiotics

Bibliography, 323

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the general characteristics of the genus *Staphylococcus*.
2. Differentiate the characteristics of staphylococci with those of other gram-positive cocci.
3. Describe the virulence factors associated with *Staphylococcus* spp. and their role in pathogenesis.
4. Compare the clinical infections associated with various staphylococcal species and the populations at greatest risk.
5. Evaluate the slide coagulase, tube coagulase, and agglutination tests for the identification of *Staphylococcus aureus*.
6. Develop a diagnostic testing algorithm to differentiate among clinically relevant *Staphylococcus* species.
7. Discuss the characteristics that should be used to identify a *Staphylococcus*-like organism isolated from a clinical sample.
8. Explain why oxacillin resistance among *S. aureus* isolates is a serious clinical problem.

9. Critique the current practices in detecting *S. aureus* resistance to oxacillin, clindamycin, and vancomycin.
10. Describe when testing with ceftiofur or testing for *mecA* or penicillin-binding protein 2a would be used.
11. Evaluate the role of present and possible future vancomycin resistance in *S. aureus* in infection control compared with that in methicillin-resistant *S. aureus* (MRSA).
12. Evaluate the role for molecular testing of MRSA among different specimen types and patient populations.
13. Explain how matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry might be used in clinical microbiology laboratories to identify *Staphylococcus* spp. and similar organisms.

 Vancomycin-resistant
Staphylococcus aureus (VRSA)

Case in point

During track practice, a 15-year-old female high school student tripped over a barrier and heard a “pop” in her right knee cap. She experienced pain in her right knee and shin and was not able to walk on that leg. The patient was seen at an emergency clinic, where it was determined that she may have torn her anterior cruciate ligament (ACL), and she was referred to an orthopedic surgeon. The damaged ACL was removed and replaced with an ACL graft, which was secured in place with screws. She was given a brace to wear for several weeks, given broad-spectrum therapy, and was to be followed up by her primary care physician within a few weeks.

During the second week of recovery, increased pain was noted in the injured knee, and a clear exudate was noted at the incision site. The site was drained, and primary cultures and antimicrobial susceptibility tests were performed at a large metropolitan laboratory. Gram-stain results showed many gram-positive cocci in pairs and clusters with few polymorphonuclear neutrophils (PMNs). Heavy growth of coagulase-positive *Staphylococcus* species grew at 18 hours. While validating a **matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF)** mass spectrometry procedure, an analysis was performed on the isolate. The MALDI-TOF report did not identify the organism as *Staphylococcus aureus*. The preliminary report was released as staphylococci species based on the MALDI-TOF identification with susceptibility results using the latest reference ranges for minimum inhibitory concentration (MIC) interpretation for this species of staphylococci. A review of the patient’s history showed that the student and her sister were frequent volunteers at a local animal shelter. The isolate, which was referred to the state health department, was identified as *Staphylococcus pseudintermedius*.

Issues to consider

After reading the patient’s case history, consider:

- Risk factors associated with acquiring this organism
- The methods that were used to identify this isolate
- Coagulase methods for staphylococci (slide, tube, and rapid) and their limitations
- The role that MALDI-TOF mass spectrometry can have in identifying common and uncommon species
- The importance of correct identification and using the latest susceptibility guidelines

Gram-positive cocci are common isolates in the clinical microbiology laboratory. Although most gram-positive cocci are members of the indigenous microbiota, some species are causative agents of serious infectious disease. This chapter discusses commonly encountered staphylococci, their characteristics, the infections they produce, and their laboratory identification. Infections caused by *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Staphylococcus saprophyticus*,

Staphylococcus lugdunensis, and *Staphylococcus haemolyticus* are emphasized.

General characteristics

The staphylococci are **catalase-positive**, gram-positive cocci. On stained smears, they exhibit spherical cells (0.5 to 1.5 µm) that appear singly, in pairs, and in clusters. The genus name, *Staphylococcus*, is derived from the Greek term *staphle*, meaning “bunches of grapes.” Although the Gram stain can be characteristic of staphylococci, microscopy alone cannot differentiate staphylococci from other gram-positive cocci. Staphylococci are members of the family Staphylococcaceae. The staphylococci are nonmotile, non-spore-forming, and aerobic or facultatively anaerobic, although a few strains are obligate anaerobes. Colonies produced after 18 to 24 hours of incubation are medium size (4 to 8 mm) and appear cream-colored, white, or rarely light gold, and “buttery-looking.”

Rare strains of staphylococci are fastidious, requiring carbon dioxide, hemin, or menadione for growth. These so-called **small colony variants (SCVs)** grow on media containing blood, forming colonies about one tenth the size of wild-type strains, even after 48 hours or more of incubation. Some species are β-hemolytic. Staphylococci are common isolates in the clinical laboratory and are responsible for numerous suppurative infections. These organisms are normal inhabitants of the skin and mucous membranes of humans and other animals.

The staphylococci resemble some members of the family Micrococcaceae, such as the genus *Micrococcus*. Micrococci are catalase-producing, coagulase-negative, gram-positive cocci found in the environment and as members of the indigenous skin microbiota. They are often recovered with staphylococci and can be differentiated easily from **coagulase-negative staphylococci (CoNS)** with the characteristics listed in [Table 14.1](#). Some micrococci have a tendency to produce a yellow pigment ([Fig. 14.1](#)). Other catalase-positive, gram-positive cocci that are occasionally recovered from human clinical specimens include *Rothia mucilaginosa* and *Alloicoccus otitis* (recovered from human middle ear fluid).

Staphylococcal species can be initially differentiated by the **coagulase** test (see procedure in [Appendix D](#) on Evolve); a positive test result is a clot formed in a tube containing plasma that is caused by staphylocoagulase. The staphylocoagulase-producing (coagulase-positive) staphylococci are *S. aureus*, *S. intermedius*, *S. pseudintermedius*, *S. hyicus*, *S. delphini*, *S. lutrae*, *S. agnetis*, and some strains of *S. schleiferi*. Isolates such as *S. lugdunensis* and *S. schleiferi* also can be occasionally mistaken for coagulase-positive staphylococci because of the presence of **clumping factor**. Clumping factor causes bacterial cells to agglutinate in plasma and was the basis of a test known as the *slide coagulase test*. This is considered an obsolete test, and only the tube coagulase test should be used for definitive testing. Rapid latex and hemagglutination assays provide presumptive identification of *S. aureus*. The principles of these tests are discussed later. The majority of clinical staphylococcal isolates that are tube coagulase positive are *S. aureus*.

The other staphylococcal species that can be positive with the traditional coagulase test are often animal-associated species and are less frequently isolated. A review of the patient

history and antimicrobial susceptibility pattern can be helpful in differentiating these less frequently isolated staphylococci species from *S. aureus*. The use of manual and automated commercial systems for identification has become routine in many laboratories. Referral to reference laboratories might be required for unusual isolates on consultation with the attending physician.

S. aureus is the most clinically significant species. It causes various cutaneous infections and purulent abscesses. These skin and soft tissue infections can be superficial, such as impetigo or cellulitis. Cutaneous infections can progress to deeper abscesses, such as **carbuncles**; involve other organ systems; and produce bacteremia and septicemia. *S. aureus* is a common cause of infective endocarditis and toxin-induced

diseases, such as food poisoning, and is associated with **scalded skin syndrome (SSS)** and **toxic shock syndrome (TSS)**.

Staphylococci that do not produce coagulase are referred to as *coagulase-negative staphylococci* (CoNS). The most clinically significant species in this group are *S. epidermidis*, *S. saprophyticus*, *S. lugdunensis*, and *S. haemolyticus*. *S. epidermidis* has been known to cause various healthcare-acquired or nosocomial infections, whereas *S. saprophyticus* is associated mainly with urinary tract infections (UTIs), predominately in adolescent girls and young women. *S. haemolyticus* is occasionally recovered from wounds, septicemia, UTIs, and native valve infections. *S. lugdunensis*, like *S. aureus*, is slide coagulase positive, so further testing, including the tube coagulase test, becomes crucial in differentiation. *S. lugdunensis* can be an aggressive pathogen and has been associated with catheter-related bacteremia and endocarditis. Because of reporting criteria, *S. lugdunensis* should be identified to the species level to provide the correct treatment options when reporting antimicrobial susceptibilities.

Currently more than 40 recognized species and subspecies of CoNS exist. Those species that have been isolated from humans are usually associated with the skin and mucous membranes; however, some are found in very specific sites, such as the head (*S. capitis*) or ear (*S. auricularis*). Some are found only in animals, but others have been associated with human disease (Table 14.2).

Clinically significant species

Staphylococcus aureus

S. aureus is responsible for numerous infections, ranging from relatively mild to life-threatening. Infections can be categorized as suppurative or toxin-mediated disease. *S. aureus* can be recovered from almost any clinical specimen and is an important cause of healthcare-associated infections. *S. aureus* is an important community-acquired pathogen, and the increasing drug resistance is a concern with this common isolate.

Virulence factors

The pathogenicity associated with *S. aureus* can be attributed to numerous virulence factors (Table 14.3), including **enterotoxins**, **cytolytic toxins**, and cellular components such as **protein A**. Several cytolytic toxins and **exfoliative toxins** have been identified. Despite these virulence factors, innate resistance to *S. aureus* is fairly high, and the organism is regarded as an opportunistic pathogen.

Enterotoxins

Staphylococcal enterotoxins are heat-stable exotoxins that cause symptoms, including diarrhea and vomiting. Numerous serologically distinct enterotoxins have been identified with the majority falling into groups A to E and G to J. These toxins are produced by 30% to 50% of *S. aureus* isolates. Because the enterotoxins are stable at 100° C for 30 minutes, reheating contaminated food does not prevent disease. Staphylococcal food poisoning is most commonly

caused by enterotoxins A, B, and D. Enterotoxins B and C and sometimes G and I are associated with TSS. Enterotoxin B has been linked to staphylococcal pseudomembranous enterocolitis. These toxins, along with **toxic shock syndrome toxin-1** (TSST-1), are superantigens and have the ability to interact with many T cells, activating an aggressive, overre-active immune response.

Toxic shock syndrome toxin-1

Previously referred to as *enterotoxin F*, TSST-1 is a chromosomal-mediated toxin that causes the majority of cases of menstruating-associated TSS and approximately 50% of non-menstruating cases. TSST-1 is a superantigen, stimulating T-cell proliferation and the subsequent production of a large number of cytokines that are responsible for the symptoms. At low concentrations, TSST-1 causes leakage by endothelial cells, and it is cytotoxic to these cells at higher concentrations. TSST-1 is absorbed through the vaginal mucosa, leading to the systemic effects seen in TSS associated with tampon use.

Exfoliative toxin

Exfoliative toxin is also known as *epidermolytic toxin*. There are two types of toxins denoted simply as *exfoliative toxin A* and *exfoliative toxin B*. They cause the epidermal layer of the skin to slough off and are known to cause staphylococcal SSS, sometimes referred to as **Ritter disease**. Ritter disease is most common in newborns and infants, with most cases reported in children younger than 5 years of age. This toxin has also been implicated in **bullous impetigo**.

Cytolytic toxins

S. aureus produces other extracellular proteins that affect red blood cells and leukocytes. These hemolysins and leukocidins are cytolytic toxins with properties different from the properties of previously described toxins. *S. aureus* produces four hemolysins: alpha, beta, gamma, and delta. **α-Hemolysin**, in addition to lysing erythrocytes, can damage platelets and macrophages and cause severe tissue damage. **β-Hemolysin** (sphingomyelinase C) acts on sphingomyelin in the plasma membrane of erythrocytes and is also called the “hot-cold” *lysin*. The “hot-cold” feature associated with this toxin is seen as enhanced hemolytic activity on incubation at 37° C and subsequent exposure to cold (4° C). This hemolysin is exhibited in the Christie, Atkins, Munch-Petersen (CAMP) laboratory test to identify group B streptococci. **δ-Hemolysin**, although found in a higher percentage of *S. aureus* strains and some CoNS, is considered less toxic to cells than either α-hemolysin or β-hemolysin. **γ-Hemolysin** is found only in association with **Panton-Valentine leukocidin** (PVL).

PVL is an exotoxin lethal to polymorphonuclear leukocytes. It has been implicated as contributing to the invasiveness of the organism by suppressing phagocytosis and has been associated with severe cutaneous infections and necrotizing pneumonia. Although produced by relatively few strains of *S. aureus*, it is often associated with community-acquired staphylococcal infections and might be a marker for such infections.

Enzymes

Several enzymes are produced by staphylococci. Examples include coagulase, protease, hyaluronidase, and lipase.

Table 14.3 Virulence factors of *Staphylococcus aureus*

Hemolysins	
α	Damages erythrocytes, platelets, and macrophages
β	Also known as <i>sphingomyelinase C</i> ; disrupts the erythrocyte plasma membranes. Responsible for CAMP assay effectiveness.
δ	Found in some CoNS strains as well as in <i>S. aureus</i> . Less toxic than other hemolysins.
γ	Associated with Pantone-Valentine leukocidin.
Pantone-Valentine leukocidin	Polymorphonuclear leukocyte toxicity
β-Lactamase	Enzyme that cleaves the ring structure of penicillins and derivative antibiotics, making them ineffective.
Penicillin-binding protein 2	Altered membrane binding protein resulting in resistance to some β-lactam antibiotics.
Hyaluronidase	Permits bacteria to spread through connective tissues.
Lipases	Common to <i>S. aureus</i> and CoNS. Degrades lipids on skin surface, making it more susceptible to bacterial entry into epidermal layers.
Staphylocoagulase	Responsible for a positive tube coagulase test result. Also present in <i>S. intermedius</i> , <i>S. pseudintermedius</i> , <i>S. hyicus</i> , <i>S. delphini</i> , <i>S. lutrae</i> , <i>S. agnetis</i> , and some <i>S. schleiferi</i> .
Toxic shock syndrome toxin-1	A superantigen causing an overreactive immune response. Formerly known as <i>enterotoxin F</i> .
Protein A	Binds IgG and prevents phagocytosis.
Enterotoxins A–E, G, J	Enterotoxins A, B, and D are the cause of the majority of staphylococcal food poisoning cases; heat stable. Enterotoxins B and C, and rarely G and I, can cause enterocolitis.
Exfoliative toxins	Also known as <i>epidermolytic toxin</i> . Types A and B. Solely responsible for SSS and present in a minority of <i>S. aureus</i> species. May also cause bullous impetigo.

CAMP, Christie, Atkins, Munch-Petersen; CoNS, coagulase-negative staphylococcus; IgG, immunoglobulin G; SSS, scalded skin syndrome.

Staphylocoagulase is produced mainly by *S. aureus*. Although the exact role of coagulase in pathogenicity is uncertain, it is considered a virulence marker. Many strains of *S. aureus* produce hyaluronidase. This enzyme hydrolyzes hyaluronic acid present in the intracellular ground substance that makes up connective tissues, permitting the spread of bacteria during infection. Lipases are produced by both coagulase-positive staphylococci and CoNS. Lipases act on lipids present on the surface of the skin, particularly fats and oil secreted by the sebaceous glands. Protease, lipase, and hyaluronidase are capable of destroying tissue and may facilitate the spread of infection to adjoining tissues.

Protein A

Protein A is one of several cellular components that have been identified in the cell wall of *S. aureus*. Probably the most significant role of protein A in infections caused by *S. aureus* is its ability to bind the Fc portion of immunoglobulin G (IgG). Binding IgG in this manner can block phagocytosis and negate the protective effects of IgG.

Epidemiology

The primary reservoir for staphylococci is the human nares, with colonization also occurring in the vagina, pharynx, axillae, and other skin surfaces. Nasal carriage in patients admitted to the hospital is common. Because contact among patients and hospital personnel is not unusual, transfer of organisms often occurs. Consequently, increased colonization in patients and hospital workers occurs frequently. Hospital outbreaks can develop in patients in nurseries and burn units and among patients who have undergone surgery or other invasive procedures. Acute care facilities are encouraged to implement strategies to prevent hospital-onset *S. aureus* bloodstream

infections. Infection control practices including hand hygiene, environmental cleaning and disinfection, and use of personal protective equipment should be routinely enforced.

In the community, intravenous drug users were estimated to be 16.3 times more likely to acquire invasive **methicillin-resistant *Staphylococcus aureus* (MRSA)** infections than others. Between 2011 and 2016, cases of invasive MRSA from injecting drugs increased from 4.1% to 9.2%. Increases in non-sterile drug injection, which can lead to increases in MRSA infections, emphasize the significance of public health interventions to prevent such infections.

Transmission of *S. aureus* may occur by direct contact with unwashed, contaminated hands and by contact with inanimate objects (fomites). Both healthcare- and community-acquired infections caused by MRSA are a major health care concern. **Decolonization** protocols have been introduced to reduce colonization for specific populations, such as patients in the intensive care unit.

Infections caused by *Staphylococcus aureus*

As with most infections, the development of staphylococcal infection is determined by the virulence of the strain, size of the infectious dose, and status of the host's immune system. Infections are initiated when a breach of the skin or mucosal barrier allows staphylococci access to adjoining tissues or the bloodstream. Any event that compromises the host's ability to resist infection encourages colonization and infection. Individuals with normal defense mechanisms are able to combat the infection more easily than individuals with impaired immune systems. Once the organism has crossed the initial barriers, it activates the host's acute inflammatory response, which leads to the proliferation and activation of polymorphonuclear cells. However, the organisms are able to

resist the action of inflammatory cells by the production of toxins and enzymes, establishing a focal lesion.

Skin and wound infections

Infections caused by *S. aureus* are suppurative. Typically, the abscess is filled with pus and surrounded by necrotic tissues and damaged leukocytes. Some common, more benign skin infections caused by *S. aureus* include **folliculitis**, **furuncles**, and **bullous impetigo**. These opportunistic infections usually occur as a result of previous skin injuries, such as cuts, burns, and surgical incisions. Folliculitis is a relatively mild inflammation of a hair follicle or oil gland; the infected area is raised and red. Furuncles (boils), which can be an extension of folliculitis, are large, raised, superficial abscesses.

Carbuncles occur when larger, more invasive lesions develop from multiple furuncles, which can progress into deeper tissues. In contrast with patients with furuncles, patients with carbuncles often present with fever and chills, indicating systemic spread of the bacteria. Bullous impetigo caused by *S. aureus* differs from streptococcal nonbullous **impetigo**, also known as *impetigo contagiosa*, in that staphylococcal pustules are larger and surrounded by a small zone of erythema. Impetigo is a highly contagious infection that is easily spread by direct contact, fomites, or autoinoculation.

Staphylococcal infections also can be secondary to skin diseases of different causes. Dry, irritated skin combined with poor personal hygiene encourages the development of infection. Some of these infections are manifested because of increased colonization of the organisms in blocked hair follicles, sebaceous glands, and sweat glands. Occasionally, these superficial infections can be misidentified as insect or spider bites. Immunocompromised individuals—particularly patients who are receiving chemotherapy, are debilitated by chronic illnesses, or have invasive devices implanted—are predisposed to developing staphylococcal infections. Infections of the skin and soft tissues can progress in seriousness and become life-threatening.

Scalded skin syndrome

SSS is a bullous exfoliative dermatitis that occurs primarily in newborns and previously healthy young children. This syndrome is caused by staphylococcal exfoliative or epidermolysin toxin produced by *S. aureus*, which is probably present at a lesion distant from the site of exfoliation. The disease has also been recognized in adults. Cases of SSS in adults occur most commonly in patients with chronic renal failure and in patients with compromised immune systems. Although the mortality rate is low (0% to 7%) in cases seen among children, the rate in adults can be 50%.

The severity of the disease ranges from a localized skin lesion in the form of a few blisters, pemphigus neonatorum, to a more extensive generalized condition affecting 90% of the body, known as *Ritter disease*. Localized lesions contain purulent material. This lesion can progress to the generalized form, which is characterized by cutaneous erythema followed by profuse peeling of the epidermal layer of the skin. The typical pattern in which the erythema occurs is origination from the face, neck, axillae, and groin and then extension to the trunk and extremities. The duration of the disease is brief, about 2 to 4 days, with complete healing occurring after around 10 days. The incidence of spontaneous recovery among children

is high, and there is scarring. The toxin is metabolized and excreted by the kidneys. It is believed that an immature or compromised renal or immune system contributes to the higher incidence of SSS among children younger than 5 years of age and among adults.

Staphylococcal SSS must be differentiated from the clinically similar toxic epidermal necrolysis (TEN), a serious, potentially fatal disease. TEN has multiple causes but is most commonly associated with drug reactions, and it has been linked to antimicrobials and anticonvulsives. The cause is unknown, but symptoms appear to be caused by a hypersensitivity reaction. Although it has a very similar initial presentation to that of SSS, treatments differ. TEN can be resolved by administration of steroids early in the initial stages of presentation, whereas steroids aggravate SSS. The mortality rate associated with TEN is high, and administration of suspected offending drugs should be stopped as soon as possible.

Toxic shock syndrome

TSS is a rare but potentially fatal, multisystem disease characterized by a sudden onset of fever, chills, vomiting, diarrhea, muscle aches, and rash, which can quickly progress to hypotension and shock. It was first described in 1978 and was associated with women using highly absorbent tampons, although some cases appeared in men, children, and nonmenstruating women. The two categories of TSS are menstruating-associated and nonmenstruating-associated. Although nonmenstruating TSS has been associated with nearly any staphylococcal infection, many cases have been seen with postsurgical infections.

Staphylococcal TSS generally results from a localized infection by *S. aureus*; only the toxin TSST-1 is systemic. The initial clinical presentation of TSS consists of high temperature, rash, and signs of dehydration, particularly if the patient has had watery diarrhea and vomiting for several days. In extreme cases, patients may be severely hypotensive and in shock. The rash is found predominantly on the trunk but can spread over the entire body. Cultures of focal lesions may yield *S. aureus*, but blood cultures are often negative. *S. aureus* does not need to be isolated to confirm the diagnosis of TSS. Supportive therapy to replace vascular volume loss is given, along with appropriate antimicrobial therapy. Most patients with TSS recover, although 2% to 5% of the cases may be fatal. The use of minimum absorbency tampons and warning label requirements from the U.S. Food and Drug Administration (FDA) for tampon products have greatly decreased the risk of TSS.

Food poisoning

S. aureus enterotoxins, most commonly A (78%), D (38%), and B (10%), have been associated with gastrointestinal disturbances. The source of contamination is usually an infected food handler. Staphylococcal food poisoning is a type of intoxication resulting from ingestion of a toxin formed outside the body. Disease occurs when food becomes contaminated with enterotoxin-producing strains of *S. aureus* by improper handling and storage, which allows growth of the bacteria and resulting toxin production. An individual ingests the food contaminated with enterotoxin and becomes ill.

Foods that are often incriminated in staphylococcal food poisoning include salads, especially salads containing

mayonnaise and eggs; meat or meat products; poultry; egg products; bakery products with cream fillings; sandwich fillings; and dairy products. Foods kept at room temperature are especially susceptible to higher levels of toxin production when contaminated with toxin-producing staphylococci. The enterotoxins do not cause any detectable odor or change in the appearance or taste of the food. Symptoms appear rapidly (approximately 2 to 8 hours after ingestion of the food) and resolve within 24 to 48 hours. Although no fever is associated with this condition, nausea, vomiting, abdominal pain, and severe cramping are common. Diarrhea and headache can also occur. Death from staphylococcal food poisoning is rare, although such cases have occurred among older adult patients, infants, and severely debilitated individuals.

Other infections

Staphylococcal bacteremia has been observed among intravenous drug users. The organisms gain entrance to the bloodstream via contaminated needles or from a focal lesion present on the skin or in the respiratory or genitourinary tract. Any local *S. aureus* infection can progress to a bacteremia leading to a secondary pneumonia, endocarditis, or bone infection. Besides producing acute, rapidly progressive disease, *S. aureus* can cause chronic infections. Often, these chronic infections are associated with SCVs. These variants are adapted for intracellular growth and are more difficult to detect on laboratory media.

Staphylococcal pneumonia has been known to occur secondary to influenza virus infection. Although relatively rare, staphylococcal pneumonia has a high mortality rate. Pneumonia, which develops as a contiguous, lower respiratory tract infection or a complication of bacteremia, is characterized by multiple abscesses and focal lesions in the pulmonary parenchyma. Infants and immunocompromised individuals, such as older adults and patients receiving chemotherapy or immunosuppressants, are most affected.

S. aureus is also associated with a number of bone infections including osteomyelitis, septic arthritis, and prosthetic joint infections. Staphylococcal osteomyelitis occurs as a manifestation secondary to bacteremia. Bacteria may lodge in the diaphysis of the long bones and establish an infection. Symptoms include fever, chills, swelling, and pain around the affected area. Septic arthritis is frequently caused by *S. aureus* in children, especially with trauma to the extremities. Septic arthritis can also occur in patients with a history of rheumatoid arthritis, diabetes mellitus, recent joint surgery, skin infections, or intravenous drug abuse. The organisms may or may not be recovered from aspirated joint fluid.

Staphylococcus epidermidis

The role of *S. epidermidis* as an etiologic agent of disease is evident. *S. epidermidis* is considered normal skin biota but is a common source of hospital-acquired infections and often a contaminant in improperly collected blood culture specimens. Some predisposing factors for hospital-acquired infection include instrumentation procedures such as catheterization, medical implantation, and immunosuppressive therapy. *S. epidermidis* infections have been associated with intravascular catheters, cerebrospinal fluid shunts, and other prosthetic devices. *S. epidermidis* is also a common cause of healthcare-acquired UTIs. Prosthetic valve endocarditis is most commonly

caused by *S. epidermidis*, although other CoNS, such as *S. lugdunensis*, have also been recovered in these cases. Septicemia has been reported in immunocompromised patients.

Infections associated with the use of implants, such as indwelling catheters and prosthetic devices, are often caused by isolates shown to produce a biofilm. Biofilm production is a key component in bacterial pathogenesis and is a complex interaction among the host, the indwelling device, and bacteria (see Chapter 31). One bacterial factor involved in adherence of *S. epidermidis* may be poly(γ -DL-glutamic acid), which provides a protective advantage against host defenses.

Staphylococcus saprophyticus

S. saprophyticus is associated with UTIs in young women. It is the second most common cause, after *E. coli*, of uncomplicated cystitis in this population. This species adheres more effectively to the epithelial cells lining the urogenital tract than other CoNS. It is rarely found on other mucous membranes or skin surfaces. When present in urine cultures, *S. saprophyticus* may be found in low numbers (<10,000 colony-forming units per milliliter) and still be considered significant.

Staphylococcus lugdunensis

S. lugdunensis can cause both community-associated and hospital-acquired infections. This organism is more virulent than others known to contain the *mecA* gene, which encodes oxacillin resistance. It is an important pathogen in infective endocarditis, septicemia, meningitis, skin and soft tissue infections, UTIs, and septic shock. Endocarditis caused by *S. lugdunensis* is particularly aggressive, frequently requiring valve replacement, and infections have a high mortality rate. The pathogenicity of this organism more closely resembles *S. aureus* than the CoNS.

Other coagulase-negative staphylococci

Species less commonly seen but established as opportunistic pathogens include *S. haemolyticus*, *S. warneri*, *S. capitis*, *S. simulans*, *S. hominis*, and *S. schleiferi*. A wide range of infections have been associated with these organisms, including endocarditis, septicemia, and wound infections. Other species of CoNS are found as normal biota in humans and animals. Although they are not commonly seen as pathogens, their role in some infections is well established, and they cannot be automatically discarded as contaminants.

S. haemolyticus is a commonly isolated CoNS. It has been reported in wounds, bacteremia, endocarditis, and UTIs. Vancomycin resistance exists in some *S. haemolyticus* isolates. Recently, *S. pseudintermedius*, a common cause of pyoderma in dogs and skin, ear, and postoperative infections in dogs and cats, has been linked to human infections. The first human case was endocarditis in a patient after implantation of a cardioverter-defibrillator device. Subsequently, other human infections reported sporadically have included surgical site infections, rhinosinusitis, and catheter-associated bacteremia. Veterinary staff and pet owners are at risk of zoonotic transmission of *S. pseudintermedius*. Many isolates contain two SCC*mec* elements (II and III) resulting in oxacillin resistance (see later). In addition, resistance to several other classes of antibiotics has been noted.

Case check 14.1

S. pseudintermedius is an opportunistic pathogen of dogs and cats commonly associated with skin, ear, and postoperative infections. This bacterium has recently been associated with a variety of infections in humans, including surgical wounds. In the Case in Point, the patient had a history of volunteering at a local animal shelter.

Laboratory diagnosis

Specimen collection and handling

Proper specimen collection, transport, and processing are essential elements in the correct diagnosis and interpretation of any bacterial culture result. Clinical materials collected from infected sites should be transported to the laboratory without delay to prevent drying, maintain the proper environment, and minimize the growth of contaminating organisms. Although the recovery of staphylococci requires no special procedures, specimens should be taken from the site of infection after appropriate cleansing of the surrounding area to avoid contamination by the skin microbiota. Normal skin biota contamination can be further reduced by the physician submitting secretion aspirates, tissue samples, or blood culture specimens instead of swabs.

Microscopic examination

Microscopic examination of stained smears prepared directly from clinical samples (Fig. 14.2) provides information that is helpful in the early diagnosis and treatment of the infection and should always be performed on appropriate specimens. Numerous gram-positive cocci along with polymorphonuclear cells in purulent exudates, joint fluids, aspirated secretions, and other body fluids, are easily seen when these sites are infected with staphylococci. A culture should be done

Fig. 14.2 Numerous gram-positive cocci in clusters, with many polymorphonuclear cells from an aspirated abscess in staphylococcal disease (Gram stain, original magnification $\times 1000$).

regardless of the results of the microscopic examination because the genus or species cannot be appropriately identified by microscopic morphology alone (Fig. 14.3). An aspirate is the best sample, whereas a single swab would be less satisfactory for both culture and smear results.

Isolation and identification

Staphylococci grow easily on routine laboratory culture media, particularly sheep blood agar (SBA). A selective medium such as mannitol salt agar (MSA), Columbia colistin–nalidixic acid agar (CNA), or phenylethyl alcohol (PEA) agar can be used for heavily contaminated specimens. The high NaCl concentration (7.5%) in MSA makes this medium selective for *Staphylococcus*, whereas the incorporation of mannitol and phenol red distinguishes *S. aureus* from most CoNS. CHROMagar Staph aureus (Becton Dickinson, Franklin Lakes, NJ) is a proprietary selective and differential medium for isolation and identification of *S. aureus*. CHROMagar MRSA can further classify *S. aureus* into MRSA or *methicillin-susceptible Staphylococcus aureus* (MSSA) strains with a higher level of sensitivity than traditional oxacillin screening methods.

Fig. 14.3 **A**, Microscopic morphology of *Staphylococcus* spp. On Gram stain, gram-negative-looking cells show how older cells decolorize ($\times 1000$). **B**, Scanning electron micrograph showing the typical “clusters” of staphylococci ($\times 20,000$).

Cultural characteristics

Staphylococci produce round, smooth, white, creamy colonies on SBA after 18 to 24 hours of incubation at 35° to 37° C. *S. aureus* can produce hemolytic zones around the colonies (Fig. 14.4) and may rarely exhibit pigment production (yellow) with extended incubation. The SCVs grow as non-pigmented, nonhemolytic pinpoint-size colonies mixed with colonies exhibiting the normal phenotype.

S. epidermidis colonies are usually small- to medium-size, nonhemolytic, gray-to-white colonies (Fig. 14.5). Some can be weakly hemolytic. *S. saprophyticus* forms slightly larger colonies, with about 50% of the strains producing a yellow pigment. *S. haemolyticus* produces medium-size colonies, with moderate or weak hemolysis and variable pigment production. Colonies of *S. lugdunensis* are often hemolytic and medium size, although small colony variants can occur. Identification of staphylococci on the basis of colony morphology alone should not be done.

Identification methods

Staphylococci have been traditionally differentiated from micrococci on the basis of oxidation-fermentation (O/F)

Fig. 14.4 *Staphylococcus aureus* growing on sheep blood agar showing β -hemolytic, creamy, buttery-looking colonies.

Fig. 14.5 Coagulase-negative staphylococci growing on sheep blood agar revealing nonhemolytic, white, creamy colonies.

reactions produced in O/F glucose medium. Staphylococci ferment glucose, whereas micrococci fail to produce acid under anaerobic conditions. However, the O/F tests do not sufficiently discern certain weak acid producers, such as *Kocuria kristinae* (formerly *Micrococcus kristinae*), and staphylococci that fail to grow or produce acid anaerobically, such as *S. saprophyticus*, *S. auricularis*, *S. hominis*, *S. xylosus*, and *S. cohnii*. Tests to differentiate micrococci from staphylococci are shown in Table 14.1. A modified oxidase test (see procedure in Appendix D on Evolve) such as the Remel Microdase Disc (Thermo Fisher Scientific, Waltham, MA) can be used to rapidly differentiate staphylococci from micrococci. Most staphylococci test negative, whereas micrococci test positive. Table 14.4 outlines key characteristics for differentiating staphylococci from other gram-positive cocci. Many commercial multitest systems have incorporated these traditional biochemical tests. In addition, molecular testing, plasmid typing, and fatty acid analysis and more recently MALDI-TOF mass spectrometry have been used for species and strain identification.

S. aureus is often identified by coagulase tests. Clumping factor, formerly referred to as *cell-bound coagulase*, causes agglutination in human, rabbit, or pig plasma. Clumping factor on the surface of the bacterial cells directly converts fibrinogen to fibrin, which precipitates onto the cell surface, causing agglutination, and this was performed on a glass slide using a heavy suspension of organism mixed with saline and a drop of plasma. A negative result was followed up by a tube coagulase test, which is described later. Because of the insensitivity of this slide test, only the tube coagulase or agglutination tests should be used.

The tube coagulase method (see Appendix D on Evolve for procedure) detects staphylocoagulase, or free coagulase. Staphylocoagulase is an extracellular molecule that causes a clot to form when bacterial cells are incubated with plasma (Fig. 14.6). Staphylocoagulase reacts with a thermostable, thrombin-like molecule called *coagulase-reacting factor* (CRF) to form coagulase-CRF complex. The coagulase-CRF complex resembles thrombin and indirectly converts fibrinogen to fibrin. The clot formed in the tube may undergo autolysis (caused by fibrinolysin), giving the appearance of a negative result. The medical laboratory scientist should look for clot formation after 4 hours of incubation at 37° C. If no clot appears, the tube should be left at room temperature and checked the next day. Fibrinolysin activity is enhanced at 37° C. Table 14.5 lists coagulase-positive staphylococci and identifies their clinical source and significance. Medical laboratory scientists must be aware that staphylococci other than *S. aureus* produce clumping factor or staphylocoagulase (Table 14.6).

Testing for *pyrrolidonyl arylamidase activity* (PYR) (see Appendix D on Evolve for procedure) can be used to differentiate *S. aureus* (negative) from *S. lugdunensis*, *S. intermedius*, and *S. schleiferi* (positive). The substrate *pyroglutamyl- β -naphthylamide* (L-pyrrolidonyl- β -naphthylamide) is hydrolyzed to L-pyrrolidone and β -naphthylamine, which combines with *p*-dimethylaminocinnamaldehyde to form a red compound. Some laboratory scientists obtain more reliable results differentiating *S. aureus* (positive) from *S. intermedius* (negative) with the Voges-Proskauer (VP) test. In the VP test, a positive result is the formation of acetoin from glucose or pyruvate. *S. intermedius* is an animal pathogen, and most human infections are associated with animal bites. *S. lugdunensis*, *S. haemolyticus*, and *S. schleiferi* are also VP test positive.

Isolates that do not produce **staphylocoagulase** are reported as CoNS. Urine isolates that are coagulase negative are tested further to identify *S. saprophyticus*. Presumptive identification of *S. saprophyticus* is accomplished by testing for novobiocin susceptibility (see [Appendix D](#) on Evolve for procedure) using a 5-μg novobiocin disk ([Fig. 14.7](#)). *S. saprophyticus* is resistant to novobiocin, whereas most other CoNS are susceptible. [Fig. 14.8](#) shows a schema for the identification of clinically significant staphylococci. [Table 14.6](#) outlines key tests for the identification of clinically significant *Staphylococcus* spp., including some CoNS.

Rapid methods of identification

Numerous commercial rapid agglutination test kits are available for differentiating *S. aureus* from CoNS. Among these are the BBL Staphyloslide (BD-BBL, Sparks, MD), Staphaurex (Thermo Fisher Scientific, Waltham, MA), and BACTiStaph (Thermo Fisher Scientific; [Fig. 14.9](#)). These kits use plasma-coated carrier particles, such as latex. The plasma detects both clumping factor (with fibrinogen) and protein A in the cell wall of *S. aureus* (with IgG). These kits often have a higher specificity and sensitivity than the traditional plasma slide test and are quicker than the tube coagulase test. Therefore they are commonly used in clinical laboratories. They are particularly useful for the identification of MRSA organisms, which are often weakly positive or negative in the slide coagulase test. Negative results should be confirmed with the tube coagulase test, nucleic acid amplification test, or MALDI-TOF mass spectrometry.

Third-generation agglutination kits, besides detecting protein A and clumping factor, contain antibodies that bind capsular antigens 5 and 8, or other surface molecules. Whereas these assays are more sensitive, they are generally less specific. False-positive results can occur with some CoNS, including *S. saprophyticus*, *S. hominis*, and *S. haemolyticus*. Careful consideration of source, colony morphology, and susceptibility pattern can eliminate some errors.

Although numerous automated and rapid multitest biochemical systems for the identification of staphylococci are available, their accuracy differs (70% to 90%). Most systems are able to identify *S. aureus*, most *S. epidermidis*, and *S. saprophyticus* strains accurately as well as some other staphylococcal species, including *S. capitis*, *S. haemolyticus*, *S. simulans*, *S. lugdunensis*, and *S. intermedius*.

Molecular methods and other rapid identification systems have been introduced into the clinical setting. Real-time polymerase chain reaction (PCR) is available for identifying both MRSA and MSSA. It has been used as an adjunct to infection control practices to reduce MRSA infections, especially in select targeted populations that would benefit from rapid testing results, such as patients in intensive care units and other select patient populations. Molecular methods are able to directly identify staphylococci from a positive blood culture sample as an aid in the diagnosis of sepsis and for targeted antimicrobial therapy treatment. Several commercial platforms, including the FilmArray BCID panel (BioFire, Durham, NC) based on multiplex PCR and the Verigene blood culture assay (Nanosphere, Northbrook, IL), which uses a proprietary chemistry method to detect nucleic acids and proteins, are available. These systems provide detection of *Staphylococcus*, *S. aureus*, and the *mecA* gene for methicillin resistance detection within 1 to 2 hours after a positive blood culture bottle has been identified.

Newer technologies, including non-PCR-based molecular techniques, are currently being evaluated, including the T2 Biosystems (Lexington, MA) and Qvella (Richmond Hill, ON) technologies for direct detection from patient blood samples, without the need of the 24- to 48-hour growth incubation phase. The major advantage of these prototype technologies is the decreased time for administration of appropriate antimicrobial therapy and likely reduced mortality and morbidity. One major disadvantage, however, is that the clinical laboratory must be able to grow the organism if antimicrobial susceptibilities are needed and, therefore, cannot rely solely

on molecular methods. Also, in the case of mixed infection, molecular methods may identify only one of the organisms present, making it essential to keep traditional methods a common practice in most cases. In comparing molecular

assays with conventional methods and the need to perform backup conventional methods, the laboratory must determine the requirements in the patient population along with the test's sensitivity, specificity, positive predictive value, and negative predictive value.

MALDI-TOF mass spectrometry continues to gain acceptance in clinical microbiology laboratories (see [Chapter 11](#)). Technologic advances, including the use of more molecular and mass spectrometry methods, are expected to increase the ability to identify staphylococci and other clinically relevant bacteria accurately and rapidly. The organism must be in a pure isolated colony and grown for a specified duration, at a specific incubation temperature, and on certain growth media. MALDI-TOF mass spectrometry cannot be used to distinguish genetic differences, such as MRSA versus MSSA strains.

Antimicrobial susceptibility

Routine testing of staphylococcal isolates can be easily performed in the laboratory using standard guidelines issued by the Clinical and Laboratory Standards Institute (CLSI). When using commercial tests, laboratories must adhere to the manufacturers' recommended procedures. Antimicrobial

Fig. 14.8 Schema for the identification of staphylococcal species. *Note:* Other *Staphylococcus* spp. that are coagulase positive besides *S. aureus* include *S. schleiferi* and *S. lugdunensis* (which can be slide test positive), *S. intermedius*, *S. pseudintermedius*, and *S. hyicus* (tube positive and slide test positive). R, Resistant; S, susceptible.

susceptibility testing of CoNS depends on the source and determination if the isolate is a contaminant or a likely pathogen. The latest interpretive standards for guidance and interpretation must be used when testing CoNS. Serious infections with *S. aureus* and *S. lugdunensis* require susceptibility testing. Because of the production of β -lactamases (penicillinases), which break down the β -lactam ring of many penicillins, most *S. aureus* isolates are resistant to penicillin. Increasing resistance to alternative antimicrobial agents is a major concern.

Methicillin-resistant staphylococci

Penicillin-resistant strains require treatment with penicillinase-resistant penicillins, such as nafcillin or oxacillin. Although methicillin is no longer used in the United States, isolates that are resistant to nafcillin or oxacillin have been traditionally termed *methicillin-resistant staphylococci*, for example, MRSA and **methicillin-resistant *Staphylococcus epidermidis*** (MRSE). Whereas MRSA has remained a serious health concern, some studies have shown a decrease in deaths in health care settings caused by invasive MRSA infections. This may be a result of more stringent infection control measures. However, since the 1990s, the incidence of **community-associated methicillin-resistant *Staphylococcus aureus*** (CA-MRSA) infections has increased (>50% of *S. aureus* isolates in some areas of the United States), and these infections can be found in patients who lack traditional healthcare-associated risk factors, such as recent hospitalization, long-term care, hemodialysis, or indwelling devices. CA-MRSA infections and outbreaks have been reported among athletes, prison inmates, military recruits in close-contact environments, pediatric patients, and tattoo recipients. Although **hospital-associated methicillin-resistant *Staphylococcus aureus*** (HA-MRSA) rates have stabilized and even declined, vigilance will still be needed to ensure that CA-MRSA rates are monitored, patient populations are educated, and adequate control measures are applied. The Centers for Disease Control and Prevention (CDC) estimates that 72,444 total MRSA cases occur annually.

MRSA infections—whether HA-MRSA or CA-MRSA infections—are costly and pose a serious threat to health institutions. Control of MRSA requires strict adherence to infection control practices, including barrier protection, contact isolation, and handwashing compliance. The use of rapid tests for MRSA may aid in the control of this agent. Vancomycin remains the treatment of choice for MRSA infection, but concerns with resistance to glycopeptides call for restrictive use of these drugs and selective reporting by the laboratory.

Case check 14.2

Based on MALDI-TOF mass spectrometry, the patient in the Case in Point was diagnosed with a *S. pseudintermedius* wound infection. This bacterium produces a positive tube coagulase test result, which could cause it to be confused with *S. aureus*. However, *S. pseudintermedius* is negative for clumping factor and should be negative in agglutination assays. Isolates are typically oxacillin resistant.

In the past, oxacillin was generally used for detection of methicillin resistance for staphylococcal species. The latest CLSI M100 document recommends that cefoxitin be used to detect oxacillin (methicillin) resistance. Cefoxitin is a better inducer of *mecA*-mediated resistance. At a minimum, the laboratory should report susceptibilities for penicillin and cefoxitin and/or oxacillin. *S. lugdunensis* has been given the same minimal inhibitory concentration breakpoint for cefoxitin as *S. aureus*, which is different from other CoNS. Some non-*S. epidermidis* strains lack *mecA*, and testing for penicillin-binding protein 2a (PBP2a) or cefoxitin disk testing might be more appropriate. Medical laboratory scientists must always refer to the latest susceptibility guides for correct interpretations. MRSA isolates should be considered resistant to all β -lactam antibiotics, including the carbapenems, except for the fifth-generation cephalosporins with MRSA activity.

MRSA populations are often heterogeneous in resistance to β -lactams, meaning one subpopulation is susceptible, whereas another is resistant to methicillin. Even though nearly all cells possess the genetic information to be resistant, only a small fraction (1 in 10^8 to 10^4 cells) expresses the resistance phenotype. Growth of the resistant subpopulation is enhanced at a neutral pH, sodium chloride concentration of 2% to 4%, cooler incubation temperature (30° to 32° C), and prolonged incubation (up to 48 hours).

Media containing oxacillin, or preferably cefoxitin, can be used to screen for MRSA in clinical samples, such as nasal specimens. These media also can differentiate MRSA isolates from isolates that are hyperproducers of β -lactamase, or **borderline oxacillin-resistant *Staphylococcus aureus* (BORSA)** strains, which would not grow on these plates. Chromogenic selective differential media, such as MRSA Select (Bio-Rad Laboratories, Hercules, CA), Spectra MRSA (Thermo Fisher Scientific), and CHROMagar MRSA (BD-BBL), have the ability to identify MRSA directly from clinical samples. High sodium chloride concentration and antimicrobial compounds such as cefoxitin are incorporated in the media and inhibit non-staphylococci and non-MRSA isolates. After 24 or 48 hours of incubation, MRSA isolates produce a colored colony, whereas MSSA and most other organisms are inhibited or produce a noncolored colony. Automated antimicrobial

susceptibility systems using cefoxitin are also generally able to identify MRSA.

Most oxacillin resistance is caused by the *mecA* gene, which is carried on a mobile cassette known as SCC_{mec}. The gene codes for an altered **penicillin-binding protein (PBP)**, PBP2a, also designated *PBP2*. The altered PBP does not bind oxacillin, rendering the drug ineffective. Latex agglutination tests are available to detect these altered PBPs, and they provide an alternative method for testing and confirmation of oxacillin resistance. This test can be performed on both CoNS and *S. aureus*.

The gold standard for MRSA detection is the detection of the *mecA* gene by using nucleic acid probes or PCR amplification. Many systems are available for direct detection from anterior nares swabs, such as the BD GeneOhm MRSA assay and the Xpert MRSA assay (Cepheid, Sunnyvale, CA) using the GeneXpert system, both of which use real-time PCR and produce results within several hours. Numerous molecular systems can identify both MRSA and MSSA in the same assay. Either type of test, with a decreased time to detection, has the potential to reduce transmission of both HA-MRSA and CA-MRSA within the hospital setting. These assays are moderate or high-complexity tests at the moment, but Clinical Laboratory Improvement Amendments–waived versions may become available as point-of-care testing in the future and could be used in nursing homes and long-term health care facilities. In addition, some PCR assays are able to identify the most common CA-MRSA strains, which are associated with a high mortality and morbidity rate and often carry the *PVL* genes. More recently, scientists in Europe have identified a new type of SCC_{mec} from a different lineage of the previously described gene. This new variant is not detected by conventional and real-time PCR assays.

CA-MRSA can cause healthcare-associated infections, and this might have an important implication in treatment and epidemiology. The Joint Commission, an accreditation agency for health care facilities, established safety goals for a laboratory-based alert system to identify MRSA, and many states already have either enacted or pending legislation requiring MRSA screening and reporting.

Vancomycin-resistant staphylococci

Vancomycin is the drug of choice and sometimes the only drug available for serious staphylococcal infections, and the development of vancomycin resistance is a serious concern for the medical community. In 1996, the first **vancomycin-intermediate *Staphylococcus aureus* (VISA)** strains were recovered in Japan. Automated antimicrobial susceptibility testing methods may be unreliable in detecting these isolates. The disk diffusion procedure also has limitations in detecting resistance. It has been suggested that clinical microbiology laboratories use more than one method to detect VISA. Because of the difficulty in identifying VISA, their incidence might be underreported. In 2002, isolates of true **vancomycin-resistant *Staphylococcus aureus* (VRSA)** were reported in the United States, isolated from patients undergoing long-term vancomycin treatment. So far, most of the isolates recovered in the United States have been from patients with underlying conditions. Detection of these isolates should be confirmed by a reference method, and reporting should follow CDC guidelines. Adherence to infection control practices

Fig. 14.10 D-zone test–positive isolate showing flattening of the clindamycin (CC) zone adjacent to the erythromycin (E) disk and the characteristic D-like pattern.

and CDC guidelines for vancomycin resistance may limit the emergence of this highly resistant organism.

Macrolide resistance

Resistance to other categories of antimicrobials such as macrolides might not always be readily apparent by routine testing. Clindamycin, a macrolide, is frequently used in staphylococcal skin infections; additional testing using a modified double-disk diffusion test (**D-zone test**) might be useful when discrepant macrolide test results are obtained (e.g., erythromycin resistant and clindamycin susceptible). Erythromycin and clindamycin susceptibility results are normally the same. However, staphylococcal resistance to clindamycin is occasionally inducible, meaning it is detectable in vitro only when the bacteria are also exposed to erythromycin.

Inducible clindamycin resistance can be detected by disk diffusion by placing an erythromycin disk near a clindamycin disk and using the latest performance standards for susceptibility testing. If an isolate possesses inducible clindamycin resistance, the bacteria grow around the erythromycin disk and in the area of the agar where the two drugs overlap. However, a zone of inhibition is observed on the side of the clindamycin disk farther away from the erythromycin disk, flattening the clindamycin zone, which looks like the letter *D* (Fig. 14.10). Some automated methods have the ability to detect this resistance. It is important for laboratories to keep up with the latest trends in antimicrobial resistance and to be aware of limitations that can occur with susceptibility testing.

POINTS TO REMEMBER

- The staphylococci are catalase-positive, gram-positive cocci.
- *Staphylococcus aureus* is the primary pathogen within this genus, and the isolation of *S. aureus* from any source should be considered clinically significant.
- *S. aureus* produces many virulence factors, including protein A, enterotoxins, toxic shock syndrome toxin-1, exfoliative toxin, cytolytic toxins, and numerous exoenzymes.

- *S. aureus* is associated with numerous diseases, including skin infections, scalded skin syndrome, toxic shock syndrome, food poisonings, bacteremia, osteomyelitis, and pneumonia.
- *Staphylococcus epidermidis* and other coagulase-negative staphylococci (CoNS) have been linked to important hospital-associated infections, often associated with foreign body implants.
- The pathogenicity of *S. lugdunensis*, a CoNS, is more like *S. aureus* than the other CoNS.
- CoNS recovered from sterile sites and sites associated with indwelling devices should be considered potential pathogens.
- HA-MRSA and CA-MRSA are important and costly health care concerns.
- *Staphylococcus saprophyticus* is an important cause of urinary tract infections, especially in younger women. The identification of *S. saprophyticus* from urine specimens should be done, especially if the bacteria are predominant, because even lower numbers can be significant.
- *S. aureus* is frequently separated from less pathogenic species by being tube coagulase positive.
- *S. saprophyticus* is resistant to novobiocin, whereas many other CoNS are sensitive.
- Increasing antimicrobial resistance is a problem with the staphylococci, particularly *S. aureus*.

LEARNING ASSESSMENT QUESTIONS

1. Which types of infections are associated with *S. aureus*?
2. In which populations are *S. aureus* infections most likely to occur?
3. How does protein A contribute to the virulence of *S. aureus*?
4. Which toxin causes toxic shock syndrome?
5. Which type of toxin is associated with staphylococcal scalded skin syndrome?
6. Which toxins are involved in staphylococcal food poisoning?
7. In which clinical condition would coagulase-negative staphylococci be significant, and in which condition might they be considered a contaminant?
8. Which coagulase-negative staphylococci are considered more significant and might need to be identified to the species level?
9. What are the two types of coagulase produced by *S. aureus*, and which one can be used as a confirmatory test for coagulase in a clinical laboratory?
10. How is *S. aureus* differentiated from similar isolates?
11. Which test is used to identify *S. saprophyticus*?
12. What is the significance of an oxacillin-resistant *S. aureus* isolate?
13. What are some risk factors associated with HA-MRSA and CA-MRSA?
14. What are the recommendations for detecting oxacillin, clindamycin, and vancomycin resistance?
15. What are the methods for identifying staphylococci?
16. Which rapid methods would be appropriate to identify a staphylococcal isolate, and when should they be used?
17. Which of the following *Staphylococcus* species is novobiocin resistant?
 - a. *S. epidermidis*
 - b. *S. saprophyticus*
 - c. *S. haemolyticus*
 - d. *S. aureus*

18. Infections following prosthetic heart valve insertion are noted in a hospital. Methicillin-resistant strains of which of the following species are associated with this condition?
 - a. *S. epidermidis*
 - b. *S. saprophyticus*
 - c. *S. haemolyticus*
 - d. *S. salivarius*
19. Culture from an infected lesion yields catalase-positive, gram-positive cocci. The colonies appear β -hemolytic, smooth, butyrous, and when tested, produce a positive tube coagulase test. Which of the following species is involved in this infection?
 - a. *S. epidermidis*
 - b. *S. saprophyticus*
 - c. *S. haemolyticus*
 - d. *S. aureus*
20. What gene encodes for oxacillin resistance in certain staphylococcal species?
 - a. *aac*
 - b. *Cat*
 - c. *mecA*
 - d. *vanA*

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Differentiate the general characteristics and isolation of streptococci and similar organisms.
2. Describe the Lancefield classification of streptococci.
3. Apply the knowledge of hemolytic patterns on sheep blood agar in the identification of streptococcal isolates.
4. Contrast the significance of streptococci and similar organisms commonly isolated in the clinical laboratory—both organisms that occur as normal biota and organisms that are potential pathogens.
5. Compare the virulence factors associated with the Streptococcaceae.
6. Explain how infections caused by the Streptococcaceae and similar organisms are established.
7. Justify the screening of women who are pregnant for group B streptococci.

8. Describe the characteristic morphology of streptococci in direct smears and from culture.
9. Given the microscopic and colony morphology of an organism isolated from a clinical sample, determine the appropriate biochemical tests for presumptive identification of the organism.
10. State the principle and purpose of each differential test used in the identification of the Streptococcaceae and similar organisms.
11. Discuss the major serologic tests used to detect antibodies that are produced after recent streptococcal infections.
12. Develop an algorithm for the identification of *Streptococcus* and *Enterococcus* species.

Case in point

A 9-year-old male complained of fever and sore throat over a 3-day period. On examination by his physician, the patient's pharynx was red, and both tonsils were swollen. Pronounced cervical lymphadenopathy was present. A swab of the tonsillar area was taken and inoculated on a sheep blood agar (SBA)

plate. After 24 hours of incubation, small, shiny, translucent colonies showing β -hemolysis were noted.

Issues to consider

After reading the patient's case history, consider:

- The most likely causative agent based on the presenting symptoms and colony morphology of the isolate
- Key tests to be performed on the bacterial isolate for identification
- Nonculture assays available for rapid identification of the isolate

In the past few decades, deoxyribonucleic acid (DNA) homology and DNA sequencing studies have led to numerous taxonomic changes to the family Streptococcaceae. The enterococci, formerly known as group D streptococci, have been classified in their own genus, *Enterococcus*. Similarly, lactococci, previously classified as group N streptococci, now belong in the genus *Lactococcus*. Although traditional phenotypic characteristics such as hemolysis and Lancefield classification (antigen serogrouping) are still useful in presumptive identification, nucleic acid studies have provided more information on the genetic relationships among different phenotypes of the members of the family Streptococcaceae. The family Streptococcaceae now includes five genera: *Streptococcus*, *Floricoccus*, *Lactococcus*, *Lactovum*, and *Okadaella*. The family Enterococcaceae includes the genus *Enterococcus* along with the genera *Bavariicoccus*, *Catelicoccus*, *Melissococcus*, *Pilibacter*, *Tetragenococcus*, and *Vagococcus*. The family Aerococcaceae includes the genera *Aerococcus*, *Abiotrophia*, *Dolosicoccus*, *Eremococcus*, *Facklamia*, *Falseniella*, *Fundicoccus*, *Globicatella*, *Hutsoniella*, *Ignavigranum*, *Ruoffia*, *Suicoccus*, and *Vaginisenealia*. This chapter presents the role of *Streptococcus* spp., *Enterococcus* spp., and other catalase-negative, gram-positive cocci in human disease, characteristics of the members in each genus, and how isolates are identified in the clinical microbiology laboratory.

General characteristics

Streptococcus and *Enterococcus* spp. are catalase-negative, gram-positive cocci that are usually arranged in pairs or chains (Fig. 15.1). A negative catalase test result differentiates streptococci and enterococci from staphylococci. Weak false-positive catalase reactions can be seen when growth is taken from media containing blood because of the peroxidase activity of hemoglobin. Compared with the cells of other gram-positive cocci, those of enterococci and some streptococci appear more elongated than spherical. The streptococcal cells are more likely to appear in chains when grown in broth cultures.

Most members of the genera *Streptococcus* and *Enterococcus* behave like facultative anaerobes. Because they grow in the presence of oxygen but are unable to use oxygen for respiration, they are considered aerotolerant anaerobes. Carbohydrates are metabolized fermentatively with lactic acid as the major end product; gas is not produced. Some species are **capnophilic**, requiring an increased concentration of carbon dioxide (CO_2), whereas the growth of other species is stimulated by an increased concentration of CO_2 , but CO_2 is not required. Growth is poor on nutrient media such as trypticase soy agar. On media enriched with blood or serum, growth is more pronounced. The colonies are usually small and transparent.

Cell wall structure

Streptococci possess a typical gram-positive cell wall consisting of peptidoglycan and teichoic acid. Most streptococci, except for many of the viridans group, have a group or common C carbohydrate (polysaccharide) that can be used to serologically classify an isolate. This classification scheme was developed in the 1930s by Rebecca Lancefield. After first recognizing the antigen in β -hemolytic streptococci, Lancefield was able to divide the streptococci into serologic groups designated by letters. Organisms in group A possess the same antigenic C carbohydrate, organisms in group B have the

Fig. 15.1 Gram stain of *Streptococcus*. A, Solid medium. B, Liquid medium.

Fig. 15.2 The streptococcal cell wall.

Table 15.1 Types of Hemolysis

Hemolysis	Description
Alpha (α)	Partial lysis of RBCs around colony Greenish discoloration of area around colony
Beta (β)	Complete lysis of RBCs around colony Clear area around colony
Nonhemolytic	No lysis of RBCs around colony No change in agar
Alpha-prime (α') or wide zone	Small area of intact RBCs around colony surrounded by a wider zone of complete hemolysis

RBC, Red blood cell.

same C carbohydrate, and so on. A schematic diagram of the streptococcal cell wall is shown in Fig. 15.2. Some species can produce a type-specific polysaccharide capsule as well.

Hemolysis

The streptococci and similar organisms can produce numerous exotoxins that damage intact red blood cells (RBCs). The types of hemolysis on sheep RBCs are described in Table 15.1. When lysis of RBCs in the agar surrounding the colony is complete, the resulting area is clear; this is termed **β -hemolysis** (Fig. 15.3). Partial lysis of the RBCs results in a greenish discoloration of the area surrounding the colony and is termed **α -hemolysis** (Fig. 15.4).

When the RBCs immediately surrounding the colony are unaffected, the bacteria are described as *nonhemolytic*. Some older references term this result *γ -hemolysis*. However, because no lysis of the RBCs occurs, the term *γ -hemolysis* is confusing and is not recommended. Some isolates belonging to the viridans group produce what is called *wide-zone* or *α' hemolysis*. The

Fig. 15.3 β -Hemolytic streptococcal colonies on sheep blood agar.

Fig. 15.4 α -Hemolytic streptococcal colonies on sheep blood agar.

colonies are surrounded by a very small zone of no hemolysis and then a wider zone of β -hemolysis. This reaction may be mistaken for β -hemolysis at first glance. The use of a dissecting microscope or handheld lens reveals the narrow zone of intact RBCs and the wider zone of complete hemolysis.

Case check 15.1

Organisms belonging to the family Streptococcaceae are catalase-negative, gram-positive cocci that are usually arranged in pairs or chains. The organisms are classified based on the hemolytic pattern on SBA and serologic grouping or typing of the C carbohydrate polysaccharide (i.e., Lancefield classification). The bacteria isolated from the patient in the Case in Point exhibited β -hemolysis on an SBA plate, and the identification was confirmed using a rapid serotyping assay.

Clinically significant streptococci and Streptococcus-like organisms

The role of streptococci and enterococci in disease has been known for more than 100 years. The range of infections caused by these organisms is wide and well-studied.

Table 15.2 Classification of *Streptococcus* and *Enterococcus*

Species	Lancefield Group Antigen	Hemolysis Types	Common Terms	Disease Association(s)
<i>S. pyogenes</i>	A	β^a	Group A streptococci	Rheumatic fever, scarlet fever, pharyngitis, glomerulonephritis, pyogenic infections
<i>S. agalactiae</i>	B	β^a	Group B streptococci	Neonatal sepsis, meningitis, puerperal fever, pyogenic infections
<i>S. dysgalactiae</i> , <i>S. equi</i>	C	β	Group C streptococci	Pharyngitis, impetigo, pyogenic infections
<i>S. bovis</i> group	D	α , none	Nonenterococcus member of viridans streptococci	Endocarditis, UTIs, nonpyogenic infections
<i>E. faecalis</i> , <i>E. faecium</i>	D	α , β , none	Enterococci	UTIs, pyogenic infections
<i>S. pneumoniae</i>	—	α	Pneumococcus	Pneumonia, meningitis, pyogenic infections
<i>Anginosus</i> group, <i>mutans</i> group, <i>mitis</i> group, <i>salivarius</i> group	A, C, F, G, N, or —	β , α , none	Viridans streptococci ^b	Usually, nonpyogenic infections, endocarditis, dental caries, abscesses in various tissues

^aOccasionally, isolates are found that are nonhemolytic.

^bAll four groups and the *S. bovis* group are referred to as viridans streptococci.

UTI, Urinary tract infection.

Some clinically important species and the diseases that they cause are listed in Table 15.2. Clinically isolated streptococci have historically been separated into β -hemolytic streptococci or **pyogenic** (pus-forming) **streptococci** and species that are non- β -hemolytic (nonpyogenic). Use of the term *pyogenic streptococci* is more precise because the group contains some species that are not β -hemolytic, and some β -hemolytic streptococci are not part of the pyogenic group. Pyogenic streptococci isolated frequently from humans include *Streptococcus pyogenes*, *Streptococcus agalactiae*, *Streptococcus dysgalactiae* subsp. *equisimilis*, *Streptococcus dysgalactiae* subsp. *dysgalactiae*, and *Streptococcus anginosus* group (some species are α -hemolytic or nonhemolytic).

Streptococcus pyogenes

Antigenic structure

S. pyogenes has a cell wall structure similar to that of other streptococci and gram-positive bacteria. The group antigen is unique, placing the organism in Lancefield **group A**. **M protein** is attached to the peptidoglycan of the cell wall and extends to the cell surface. The M protein is essential for virulence.

Virulence factors

The best-defined virulence factor in *S. pyogenes* is M protein, encoded by the *emm* gene. The M-protein molecule causes the streptococcal cell to **resist phagocytosis** and plays a role in adherence of the bacterial cell to mucosal cells. Like staphylococcal protein A, M-protein can bind the fragment crystallizable (Fc) of human antibody; however, this effect on virulence is unknown. More than 200 different serotypes and subtypes of M protein exist, identified as M1 (*emm1*), M2 (*emm2*), etc. Resistance to infection with *S. pyogenes* appears to be related to the presence of type-specific antibodies to the M protein.

This means that an individual with antibodies against M5 is protected from infection by *S. pyogenes* with the M5 protein but remains unprotected against infection with the roughly 200 remaining M-protein serotypes. **The M1 serotype is the most common serotype seen in pharyngitis.** More recently, microarray analyses of group A streptococci (GAS) serotype M1 isolates have been useful in identifying the genes associated with pharyngitis versus invasive disease. M-like proteins, encoded by the *Enn* and *Mrp* genes, are additional surface proteins with similar functions as M protein. M and M-like proteins bind the **Fc portion of immunoglobulin G, immunoglobulin A, or both.** A study of 1,688 global isolates of group A streptococci found that 85% encoded both *Enn* and *Mrp* proteins.

Additional virulence factors associated with **GAS include fibronectin-binding protein (protein F), lipoteichoic acid, hyaluronic acid capsule, and extracellular products including hemolysins, toxins, and enzymes.** Lipoteichoic acid and protein F are adhesion molecules that mediate attachment to host epithelial cells. Lipoteichoic acid, which is affixed to proteins on the bacterial surface, in concert with M proteins and fibronectin-binding protein, secures the attachment of streptococci to the oral mucosal cells. The hyaluronic acid capsule of *S. pyogenes* is weakly immunogenic. **The capsule prevents opsonized phagocytosis by neutrophils or macrophages.** The capsule also allows the bacterium to mask its antigens and remain unrecognized by its host's immune system.

Other **products** produced by *S. pyogenes* include **streptolysin O (SLO)**, streptolysin S, deoxyribonuclease (DNase), streptokinase, hyaluronidase, and erythrogenic exotoxins capable of producing an **erythematous sandpaper-like rash.** Although all of these products have been postulated to play a role in virulence, the exact role each has in infection is unclear. *S. pyogenes* **secretes four different DNases:** A, B, C, and D. All strains produce at least one DNase; the most common is DNase B. These enzymes are antigenic, and antibodies to DNase can be detected after infection.

SLO is responsible for hemolysis on SBA plates incubated anaerobically. The O refers to this hemolysin being oxygen labile. It is active only in the reduced form, which is achieved in an anaerobic environment. SLO lyses leukocytes, platelets, and other cells as well as RBCs. SLO is highly immunogenic, and infected individuals readily form antibodies to the hemolysin. These antibodies can be measured in the antistreptolysin O (ASO) test to determine whether an individual has had a recent infection with *S. pyogenes*. **Streptolysin S** is oxygen stable, lyses leukocytes, and is nonimmunogenic. The hemolysis seen around colonies incubated aerobically is caused by streptolysin S.

GAS cause the lysis of fibrin clots through the action of streptokinase on plasminogen. The plasminogen is converted into a protease (plasmin), which lyses the fibrin clot. Antibodies to streptokinase can be detected after infection but are not specific indicators of GAS infection because group C and G streptococci also form streptokinase. **Hyaluronidase**, or spreading factor, is an enzyme that solubilizes the ground substance of mammalian connective tissues (hyaluronic acid). It was postulated that the bacteria use this enzyme to separate the tissue and spread the infection; however, no evidence to support this hypothesis exists.

Some strains of *S. pyogenes* cause a red spreading rash, referred to as scarlet fever, caused by streptococcal pyrogenic exotoxins, formerly called erythrogenic toxins. The four immunologically distinct exotoxin types found in *S. pyogenes* are SpeA, SpeB, SpeC, and SpeF. These toxins function as superantigens. Streptococcal superantigens belong to a family of highly mitogenic proteins secreted individually or in combinations by many *S. pyogenes* strains. These proteins share the ability to stimulate T-lymphocyte proliferation by interaction with class II major histocompatibility complex (MHC) molecules on antigen-presenting cells and specific variable β chains of the T-cell receptor. This interaction results in the production of interleukin-1, tumor necrosis factor, and other cytokines that appear to mediate the disease processes associated with these toxins.

Clinical infections

S. pyogenes colonizes the throat and skin on humans, making these sites the primary sources of transmission. Infections resulting from *S. pyogenes* include pharyngitis, scarlet fever, skin or pyoderma infections, and other septic infections. In addition, the sequelae rheumatic fever and acute glomerulonephritis can occur as a result of infection with *S. pyogenes*.

Bacterial pharyngitis

The most common clinical manifestations of GAS infection are pharyngitis and tonsillitis. Most cases of bacterial pharyngitis are caused by *S. pyogenes*. Streptococci from other groups, particularly C and G, have the capability to produce significant acute pharyngitis but are less commonly seen.

Streptococcal pharyngitis or "strep throat" is most often seen in children between 5 and 15 years of age. After an incubation period of 1 to 4 days, an abrupt onset of illness ensues, with sore throat, malaise, fever, and headache. Nausea, vomiting, and abdominal pain are not unusual. The tonsils and pharynx are inflamed. The cervical lymph nodes are swollen and tender. The disease ranges in intensity, and these symptoms may not be seen. It is not unusual to isolate a nearly

pure culture of *S. pyogenes* from the throat of a child with fever and complaint of only a mild sore throat. The symptoms subside within 3 to 5 days unless complications, such as peritonsillar abscesses, occur. The disease is spread by droplets and close contact. Although clinical criteria have been proposed, the diagnosis of streptococcal sore throat relies on a throat culture, direct antigen detection, nucleic acid probe, or nucleic acid amplification tests. About one third of children complaining of sore throat have a throat culture positive for *S. pyogenes*. An estimated 600 million cases of pharyngitis caused by GAS occur each year worldwide.

Case check 15.2

The patient in the Case in Point presented with classic symptoms of streptococcal pharyngitis, although other infectious agents can produce similar symptoms. M protein is the main virulence factor in *S. pyogenes*. Other virulence factors include fibronectin-binding protein (protein F); lipoteichoic acid; hyaluronic acid capsule; and extracellular products, including hemolysins, toxins, and enzymes. Antibodies to oxygen-labile SLO can be used to diagnose recent infection.

Pyoderma infections

Skin or pyoderma infections with GAS result in impetigo, cellulitis, erysipelas, wound infection, or arthritis. **Impetigo**, a localized skin disease, begins as small (nonbullous) vesicles that progress to weeping lesions. The lesions crust over after several days. Impetigo is usually seen in young children (2 to 5 years of age) and affects exposed areas of the skin. Inoculation of the organism occurs through minor abrasions or insect bites. *Staphylococcus aureus* produces a bullous form of impetigo. **Erysipelas** is a rare infection of the skin and subcutaneous tissues observed frequently in older adult patients. It is characterized by an acute spreading skin lesion that is intensely erythematous with a plainly demarcated but irregular edge. **Cellulitis** can develop following deeper invasion by streptococci. The infection can be serious or life-threatening with bacteremia or sepsis. In patients with peripheral vascular disease or diabetes, cellulitis can lead to gangrene.

Infection with strains of *S. pyogenes* that produce streptococcal pyrogenic exotoxins can result in scarlet fever. Strains of *S. pyogenes* infected with the temperate bacteriophage T12 produce streptococcal pyrogenic exotoxins. Scarlet fever, which appears within 1 to 2 days after bacterial infection, is characterized by a diffuse red rash that appears on the upper chest and spreads to the trunk and extremities. The rash disappears over the next 5 to 7 days and is followed by desquamation.

Necrotizing fasciitis

GAS have been associated with necrotizing fasciitis (NF), an invasive infection characterized by rapidly progressing inflammation and necrosis of the skin, subcutaneous fat, and fascia. The most common serotypes associated with NF are M1, M3, M12, and M28. Although uncommon, NF is a life-threatening infection. The Centers for Disease Control and Prevention (CDC) tracks NF caused by GAS. Since 2010, approximately 700 to 1100 cases of NF have occurred annually in the United States; however, this is likely an underestimation as some cases are probably not reported. NF occurs most frequently in individuals who have other health problems.

Death can be prevented if early intervention is instituted; the mortality rate may reach greater than 70% if the infection is left untreated. Many different bacteria can cause destruction of the soft tissue in this manner, a clinical feature that has been described as *flesh-eating disease*. Depending on which organisms are cultured, NF may be categorized as type 1, 2, or 3. A polymicrobial infection from which aerobic and anaerobic bacteria are recovered is categorized as type 1 NF. **Type 2 NF consists of only GAS.** Type 3 is gas gangrene or clostridial myonecrosis. A variant of type 1 NF is saltwater NF, in which an apparently minor skin wound is contaminated with saltwater containing a *Vibrio* species, such as *Vibrio vulnificus*.

Cases of NF were described in the 18th century, but the term was not conceived until 1952. In addition to *flesh-eating bacteria syndrome*, other terms for NF have included *suppurative fasciitis*, *hospital gangrene*, and *necrotizing erysipelas*. NF can occur as a result of trauma, such as burns and lacerations. The break in the skin may become the portal of entry for the bacteria. However, NF infections caused by GAS occur in young, healthy individuals, and a break in the skin that served as portal of entry is not found in many cases. Good wound care is important in minimizing the risk of NF.

Streptococcal toxic shock syndrome

The reemergence of streptococcal toxic shock syndrome (TSS) in the 1980s remains largely unexplained. Streptococcal TSS is a condition in which the entire organ system collapses, leading to death. The exact portal of infection is unknown for most cases of streptococcal TSS, **although minor injuries or surgical procedures have been implicated.** The initial streptococcal infection is often severe (e.g., pharyngitis, peritonitis, cellulitis, wound infections), and the symptoms that develop are similar to symptoms of staphylococcal TSS. Patients are often bacteremic and have NF.

GAS associated with streptococcal TSS produce a streptococcal pyrogenic exotoxin, notably SpeA. These toxins likely play a major role in the pathogenesis of this disease functioning as superantigens, leading to overstimulation of the immune response, resulting in cytokine production (cytokine storm). Other virulence factors, such as SLO and various cell wall antigens, can also contribute to toxic shock. Isolates with M1 and M3, which account for about 50% of cases, are the most common strains associated with streptococcal TSS. Young children, especially children with chickenpox (varicella), and older adults seem to be at greatest risk.

Poststreptococcal sequelae

Two serious complications, or sequelae, of **GAS disease are rheumatic fever and acute glomerulonephritis.** Rheumatic fever typically follows *S. pyogenes* pharyngitis. It is characterized by fever and inflammation of the heart, joints, blood vessels, and subcutaneous tissues. Attacks usually begin within **1 month after infection.** The most serious result is chronic, progressive damage to the heart valves. Repeated infections can produce further valve damage. In some instances, antibodies from streptococcal sequelae cross-react with the brain to produce a neurologic manifestation of **acute rheumatic fever called Sydenham chorea.** Rheumatic fever is rare in most developed countries, and it is no longer a reportable disease in the United States. Acute rheumatic fever and its chronic sequela, rheumatic heart disease, remain problematic in developing countries and in some poor populations in

industrialized countries. The pathogenesis of rheumatic fever is caused by antigenic cross-reactivity between streptococcal antigens and heart tissue.

Acute glomerulonephritis sometimes occurs after a cutaneous or pharyngeal infection. It is more common in children than in adults. The pathogenesis appears to be immunologically mediated. Circulating immune complexes are found in the plasma of patients with acute glomerulonephritis, and it is postulated that these antigen-antibody complexes deposit in the glomeruli. Complement is subsequently fixed, and an inflammatory response causes damage to the glomeruli, resulting in impairment of kidney function.

GAS are susceptible to penicillin, which remains the drug of choice for treatment. For patients who are allergic to penicillin, erythromycin can be used. For patients who have a history of rheumatic fever, prophylactic doses of penicillin are given to prevent recurrent infections that might cause additional damage to the heart valves.

Laboratory diagnosis

An essential step in the diagnosis of streptococcal pharyngitis is proper sample collection. The tongue should be depressed, and the swab rubbed over the posterior pharynx and each tonsillar area. If exudate is present, it should also be touched with the swab. Care should be taken to avoid the tongue and uvula. **Examination of Gram stains of upper respiratory tract specimens or skin swabs is of little value because these areas have considerable amounts of gram-positive cocci as part of the normal bacterial biota.**

Transport media are not required for normal conditions. The organism is resistant to drying and can be recovered from swabs several hours after collection. **Desiccation can enhance the recovery of *S. pyogenes* by causing the loss of viability of normal microbiota.** An SBA plate is inoculated and streaked for isolation. Incubation should be at 35°C either in ambient air or **under anaerobic conditions.** The normal respiratory microbiota tends to overgrow β -hemolytic streptococci when incubated in increased concentration of CO₂. Several **selective media**, such as SBA with phenylethyl alcohol, sulfamethoxazole (SMZ), or colistin and polymyxin B found in some formulations of *Streptococcus* selective agar, have been recommended for better recovery of β -hemolytic streptococci from throat cultures. The plate is observed after 24 hours for the presence of β -hemolytic colonies. If none are found, incubation should continue for an additional 24 hours before the culture is reported as negative. False-negative results can occur from overgrowth of normal microbiota and lack of β -hemolysis.

Colonies of *S. pyogenes* on SBA are small, transparent, and smooth with a well-defined area of β -hemolysis. Gram stain reveals gram-positive cocci with some short chains. Suspect colonies can be Lancefield-typed using serologic methods, which gives a definitive, rapid identification, or biochemical tests can be performed. The correlation between presumptive identification using biochemical methods and the rapid definitive serologic method is high. Most clinical laboratories choose to use serologic methods. Key tests include bacitracin susceptibility or **pyrrolidonyl- α -naphthylamide (PYR) hydrolysis.** ***S. pyogenes* is susceptible to bacitracin and hydrolyzes PYR,** whereas most other β -hemolytic groups are resistant to bacitracin and are PYR-negative. The best way to differentiate group C and G streptococci from GAS

is Lancefield typing. Group C streptococci are generally sensitive to bacitracin. Bacitracin resistance is variable among group G streptococci.

When the origin of an isolate is not the throat (i.e., blood or sputum) and serologic identification is not used, the following tests should be part of the early identification scheme in addition to PYR and bacitracin susceptibility testing: hippurate hydrolysis; Christie, Atkins, Munch-Peterson (CAMP) test; bile esculin test; and growth in 6.5% sodium chloride (NaCl) broth. The reactions of some catalase-negative, gram-positive cocci in various biochemical tests are outlined in Table 15.3. Immunologic tests used to detect infection with *S. pyogenes* include ASO, anti-DNase, antistreptokinase, and antihyaluronidase titers.

Rapid antigen detection tests (RADTs) may be used to diagnose GAS pharyngitis at the point of care. These rapid tests detect *S. pyogenes*-specific cell wall antigens by enzyme immunoassays or optical immunoassays. Sensitivities of 90% in adults and 80% to 90% in children have been reported. In children, a negative RADT result should be confirmed with throat cultures. Rapid polymerase chain reaction (PCR) assays such as the Lyra Direct Strep assay (Quidel Corporation, San Diego, CA), Liat Strep A assay (Roche Diagnostics, Indianapolis, IN), and Simplexa Group A Strep Direct test (Focus Diagnostics, Cypress, CA), among others, are available for the detection of *S. pyogenes* in throat swabs in the hospital setting.

Commercial systems for direct identification of streptococci from blood cultures include the Verigene gram-positive blood-culture (BC-GP) nucleic acid test (Luminex, Austin, TX) and the FilmArray blood culture identification (BCID) panel (bioMérieux, Durham, NC). Misidentification of *S. dysgalactiae* subsp. *equisimilis* as *S. pyogenes* has been reported with matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry bacterial identification systems (Bruker, Billerica, MA).

Streptococcus agalactiae

Antigenic structure

All strains of *S. agalactiae* have the group B-specific antigen, an acid-stable polysaccharide located in the cell wall. *S. agalactiae* is the only species that expresses group B antigen. Additionally, there are nine recognized capsular polysaccharide serotypes. These type-specific antigens can be detected by precipitin tests. Serotypes Ia, Ib, and II contain a terminal residue of sialic acid, which is weakly immunogenic and can inhibit activation of the alternative complement pathway.

Virulence factors

The capsule is an important virulence factor in infections with group B streptococci (GBS). Antibodies against the type-specific antigens protect mice against strains of *S. agalactiae* with the homologous polysaccharide in the capsule. The capsule prevents phagocytosis but is ineffective after opsonization. Sialic acid appears to be the most significant component of the capsule and a critical virulence determinant. Studies with mutant strains of *S. agalactiae* showed that the loss of capsular sialic acid was associated with loss of virulence. Other products produced by *S. agalactiae* include a hemolysin,

CAMP factor, neuraminidase, DNase, hyaluronidase, and protease. No evidence exists that any of these products play a role in the virulence of this organism.

Clinical infections

GBS were known for many years as the cause of mastitis in cattle. It was not until Lancefield defined streptococcal classification in the 1930s that their role in human disease was recognized. *S. agalactiae* was identified in the 1970s as a significant cause of invasive disease in the newborn, and it remains so today. GBS are the leading cause of death in infants in the United States, although the incidence decreased dramatically from the 1990s to 2008. Two clinical syndromes are associated with neonatal GBS disease: early-onset infection (<1 week of age) and late-onset infection (at least 1 week of age to about 3 months of age). Early-onset disease accounts for about 80% of the clinical cases in newborns and is caused by vertical transmission of the organism from the mother. Colonization of the vagina and rectal area with GBS is found in 10% to 30% of pregnant women.

Most infections of infants occur in the first 3 days after birth, usually within 24 hours. This infection is commonly associated with obstetric complications, prolonged rupture of membranes, and premature birth. Early-onset infection often manifests itself as pneumonia and sepsis, and late-onset infection manifests itself as meningitis and sepsis. Serotype III GBS clone ST-17 is reported to be responsible for the majority of the early- and late-onset infections worldwide. The mortality rate in GBS-infected infants is high, and death usually occurs if treatment is not started quickly.

The most important determining factor in early-onset infection is the presence of GBS in the vagina of the mother. It is recommended that all pregnant women be screened for GBS at 35 to 37 weeks' gestation. Screening methods are discussed later. As mentioned earlier, late-onset infection occurs between 1 week and 3 months after birth and usually manifests itself as meningitis. This infection is uncommonly associated with obstetric complications. Also, the organism is rarely found in the mother's vagina before birth. The mortality rate is considerably less than the mortality rate associated with early-onset disease, but it is high enough to be of serious concern.

The incidence of GBS infections decreases dramatically after the neonatal period. In adults, the infection affects two patient types. One type is a young, previously healthy woman who becomes ill after childbirth or abortion; endometritis and wound infections are most common. In addition, tricuspid valve endocarditis is sometimes observed in young women undergoing obstetric procedures. The second type of patient is an older adult with a serious underlying disease or immunodeficiency. In this patient population, GBS infection manifests itself as skin and soft tissue infections, intraabdominal abscess, bacteremia, or pneumonia. Other infections such as endocarditis and urinary tract infections (UTIs) have also been reported.

The drug of choice for treating GBS infections is penicillin, although GBS are less susceptible to penicillin than GAS. The clinical response to antimicrobial therapy is often poor despite the heavy doses given. Some clinicians recommend a combination of ampicillin and an aminoglycoside for treating GBS infections. Despite the increased use of prophylactic

antimicrobials in pregnant women, *S. agalactiae* has remained susceptible to penicillin and cephalosporins; however, increasing minimal inhibitory concentrations (MICs) have been reported.

Laboratory diagnosis

GBS grow on SBA as grayish white mucoid colonies surrounded by a small zone of β -hemolysis (Fig. 15.5). These organisms are gram-positive cocci that form short chains in clinical specimens and longer chains in culture. Presumptive identification is based on biochemical reactions. The most useful tests are hippurate hydrolysis and CAMP tests. These tests enable the organism to be readily differentiated from other β -hemolytic streptococcal isolates. Fig. 15.6 demonstrates how susceptibility to the Bacitracin disk and the CAMP test can be used to differentiate *Streptococcus* spp. The definitive identification can be made by extracting the group antigen and demonstrating agglutination with specific anti-group B antisera.

Fig. 15.5 *Streptococcus agalactiae* colony growing on sheep blood agar.

Fig. 15.6 Schematic diagram for differentiation of group A streptococci from group B streptococci. CAMP, Christie, Atkins, Munch-Petersen test.

Detection of GBS in pregnant women is accomplished by collecting vaginal and rectal material with swabs between 35 and 37 weeks' gestation. Samples should be inoculated into selective broth, such as Todd-Hewitt broth containing 10 μ g/mL colistin and 15 μ g/mL nalidixic acid (Lim broth; BD Diagnostic Systems, Sparks, MD). Broth containing 8 μ g/mL gentamicin and 15 μ g/mL nalidixic acid (TransVag broth, Thermo Fisher Scientific, Waltham, MA) may also be used. The inoculated media are incubated at 35°C for 18 to 24 hours before being subcultured to SBA. Numerous nucleic acid amplification tests for nonenriched clinical specimens and culture-enriched specimens are available. The BD MAX GBS Assay (BD Diagnostic Systems) is a fluorescence-based PCR assay that can be used to detect GBS in broth and determine GBS colonization in antepartum women.

Chromogenic agar that changes color if β -hemolytic GBS are present can be used in place of SBA when performing subcultures from broth or used for direct plating of clinical specimens. Cultures are examined for colonies resembling GBS after 24 hours of incubation at 35°C in an incubator containing 5% CO₂. Cultures that do not show colonies resembling GBS are incubated for an additional 24 hours.

StrepB Carrot Broth (SCB; Hardy Diagnostics, Santa Maria, CA), which can be substituted for Lim or TransVag broth, was shown to have improved diagnostic value and efficiency. Vaginal or rectal swabs are placed into SCB and incubated for 18 to 24 hours at 35°C. β -Hemolytic GBS often produce an orange or red pigment in SCB after incubation for 6 hours. Further identification is unnecessary. Isolates that are non-hemolytic do not produce a color change, requiring that the broth be subcultured. Approximately 4% of invasive isolates are nonhemolytic.

The CDC recommends universal vaginal and rectal screening of all pregnant women during the late third trimester. Women who test positive should receive prophylactic antimicrobial therapy. Additional women who should be treated include those who had a urine culture positive for GBS any time during the pregnancy, a history of an infant with GBS disease, and an unknown GBS status at the time of delivery (culture was not done). The CDC also recommends screening pregnant women for asymptomatic bacteriuria. GBS should be identified and reported to the primary care provider when the colony count is greater than or equal to 10⁴/mL in either pure culture or mixed with a second microorganism. These preventive measures help reduce the risk of early-onset GBS infection but are not likely to affect late-onset infections significantly.

Group C and G streptococci

In the most recent classification of β -hemolytic streptococci, isolates from humans that belong to Lancefield groups C and G are subdivided into large-colony (diameter >0.5 mm after 24 hour incubation) and small-colony forms (diameter <0.5 mm after 24 hour incubation). The large-colony-forming isolates with group C and G and sometimes group A and L antigens are classified with the pyogenic streptococci. The large-colony-forming β -hemolytic isolates with group A, C, G, or L antigens belong to *S. dysgalactiae* subsp. *equisimilis*. The small-colony-forming β -hemolytic isolates with group A, C, F, or G antigens belong to the *S. anginosus* group, which are included in the viridans streptococci, discussed later.

Clinical infections by *S. dysgalactiae* subsp. *equisimilis*, although uncommon, have involved several body sites and are thought to be uncommon in domestic animals. The spectrum of infections resembles that of *S. pyogenes* and includes upper respiratory tract infections, skin infections, soft tissue infections, and invasive infections such as NF. Because several antigenic groups are included within the species, serotyping of *S. dysgalactiae* to determine the species is complex. *S. equi* subsp. *zooepidemicus*, which also expresses C antigen, is primarily an animal pathogen rarely isolated from humans. It has been associated with cases of glomerulonephritis and rheumatic fever after infections.

Streptococcus pneumoniae

Antigenic structure

Also known as *pneumococcus*, *S. pneumoniae* is isolated from a variety of clinical specimens. *S. pneumoniae* is a member of the *S. mitis* group, but it is much more virulent than other members of the group. The cell wall of *S. pneumoniae* contains an antigen, referred to as C substance, that is similar to the C carbohydrate of the various Lancefield groups. A β -globulin in human serum, called C-reactive protein (CRP), reacts with C substance to form a precipitate. This is a chemical reaction and not an antigen-antibody combination. The amount of CRP increases during inflammation and infection.

S. pneumoniae can express 1 of over 100 different capsular types based on chemical variations of the capsular polysaccharide. Antibody directed against the capsular antigen is protective. Isolates from certain sources—for example, cases of lobar pneumonia—show a predominance of particular capsular types. The capsule is antigenic and can be identified with appropriate antisera in the Neufeld test. In the presence of specific anticapsular serum, the capsule swells (Quellung reaction). This reaction not only allows identification of *S. pneumoniae* but also serves to specifically serotype the isolate.

Virulence factors

The characteristic of *S. pneumoniae* that is clearly associated with virulence is the capsular polysaccharide. Strains that have lost the ability to produce a capsule are nonpathogenic. In addition, opsonization of the capsule renders the organism avirulent. Several toxins are produced, including a hemolysin, an immunoglobulin A protease, neuraminidase, and hyaluronidase. None of these have been shown to have a role in disease production.

Clinical infections

S. pneumoniae is a common isolate in the clinical microbiology laboratory. It is an important human pathogen that causes pneumonia, sinusitis, otitis media, bacteremia, and meningitis. *S. pneumoniae* is the most frequently encountered isolate in children younger than 3 years of age with recurrent otitis media. *S. pneumoniae*, the leading cause of bacterial pneumonia, is especially prevalent in older adults and in patients with underlying disease. Of the over 100 capsular serotypes, about one fourth account for most pneumococcal pneumonia cases. In a U.S. study from 2015 to 2016, 26 serotypes accounted for 98% of the *S. pneumoniae* isolates. Despite being a component of pneumococcal vaccines, serotype 3 was the most common

isolate (657/5334; 12.3%). Various studies have indicated that serotype 3 is linked to some of the most severe infections, such as empyema, bacteremia, cardiotoxicity, and meningitis, with a fatality rate of 30% to 47%.

For an individual to contract pneumococcal pneumonia, the organism must be present in the nasopharynx, and the individual must be deficient in the specific circulating antibody against the capsular type of the colonizing strain of *S. pneumoniae*. After initial colonization, the bacteria can persist for weeks or months without causing disease. In some individuals, invasive disease occurs that leads to community-acquired pneumonia.

Pneumonia resulting from *S. pneumoniae* is not usually a primary infection but is rather a result of disturbance of the normal defense barriers. Predisposing conditions, such as alcoholism, anesthesia, malnutrition, and viral infections of the upper respiratory tract, can lead to pneumococcal disease in the form of lobar pneumonia. Older adults are also at increased risk for infection. The infection begins with aspiration of respiratory secretions, which often contain pneumococci. In the alveoli, the organisms stimulate an outpouring of fluid, which facilitates the spread of the organism to adjacent alveoli. The process stops when the fluid reaches fibrous septa that separate the major lung lobes. This accounts for the “lobar” distribution of the infection—hence the name. Pneumococcal pneumonia is characterized by sudden onset of chills, dyspnea, and cough.

Pneumonia may be complicated by a pleural effusion that is usually sterile (empyema). The laboratory might receive fluid from a pleural aspirate for culture. An infected effusion contains many white blood cells and pneumococci, which are visible on Gram stain. Even with antimicrobial therapy, mortality is relatively high (5% to 10%); however, without therapy, the mortality rate approaches 50%. Pneumococcus causes bacterial meningitis in all age groups. Meningitis usually follows other *S. pneumoniae* infections, such as otitis media or pneumonia. The course of the disease is rapid, and the mortality rate is near 40%. Direct smears of the cerebrospinal fluid often reveal leukocytes and numerous gram-positive cocci in pairs. Pneumococci may also be involved in other infections, such as endocarditis, peritonitis, and bacteremia. Bacteremia often occurs during the course of a serious infection. Consequently, samples for blood culture are often taken simultaneously with sputum or a fluid aspirate.

Currently, three pneumococcal conjugate vaccines (PCVs) are available. PCV13, protecting against 13 serotypes commonly affecting children, is composed of purified polysaccharides conjugated to a diphtheria protein and is approved for use in children. This vaccine is part of the routine pediatric immunization schedule encompassing four doses beginning at 2 months of age. PCV15 is recommended for individuals 19 to 64 years of age, and PCV20 is recommended for people 65 years or older who have not previously received a pneumococcal conjugate vaccine. The 23-valent pneumococcal polysaccharide vaccine (PPSV23), composed of 23 purified capsular polysaccharides, is used for adults. Vaccination is recommended for all individuals older than 65 years of age or individuals with a long-term health problem (e.g., asplenic individuals or patients with diabetes, leukemia, lymphoma, or human immunodeficiency virus infection). Typically, only a single dose is needed. The vaccine has been successful in reducing the incidence and severity of pneumococcal disease. Epidemiologic surveys report an increase in infections resulting from serotypes not covered by the vaccine serotypes.

Laboratory diagnosis

The cells characteristically seen on Gram stain appear as gram-positive cocci in pairs (diplococci). The ends of the cells are slightly pointed, giving them an oval or lancet shape (Fig. 15.7). The cocci can occur singly or in short chains but most often are seen in pairs. As the culture ages, the Gram stain reaction becomes variable, and gram-negative cells are seen. The capsule can be demonstrated by using a capsule stain.

The nutritional requirements of *S. pneumoniae* are complex. Media such as brain-heart infusion agar, trypticase soy agar with 5% sheep RBCs, or chocolate agar are necessary for good growth. Some isolates require increased CO₂ concentration for growth during primary isolation. Isolates produce a large zone of α -hemolysis on SBA surrounding the colonies. Young cultures have a round, glistening, wet, mucoid, dome-shaped appearance (Fig. 15.8). As the colonies become older, autolytic changes result in a collapse of each colony's center, giving it the appearance of a coin with a raised rim. The tendency of *S. pneumoniae* to undergo autolysis can make it difficult to keep isolates alive. Clinical isolates and stock cultures require frequent subculturing (every 1 to 2 days) to ensure viability.

Fig. 15.7 Gram stain of *Streptococcus pneumoniae*. Direct smear of sputum from a patient with pneumonia caused by *S. pneumoniae*. The clear, nonstained area around the organism represents the capsule. ($\times 1000$).

Fig. 15.8 *Streptococcus pneumoniae* colonies on sheep blood agar. The colonies demonstrate a characteristic mucoid appearance and a concave center.

The colonies may closely resemble colonies of the viridans streptococci, and the greatest concern in the laboratory diagnosis is distinguishing *S. pneumoniae* from the viridans streptococci. However, a presumptive differentiation is not difficult to make. Optochin susceptibility and bile solubility tests are used to accomplish this; the optochin susceptibility test is more commonly used. The optochin susceptibility test takes advantage of the fact that *S. pneumoniae* is susceptible to optochin, whereas other α -hemolytic species are resistant. The bile solubility test determines the lysis of *S. pneumoniae* in the presence of bile salts. It correlates with optochin susceptibility; that is, *S. pneumoniae* isolates are optochin susceptible and bile soluble. The Phadebact pneumococcus test (MKL Diagnostics, Sollentuna, Sweden), is a rapid test for the identification of culture isolates. The coagglutination assay uses anticapsular antibodies produced in rabbits. Currently, many clinical microbiology laboratories are starting to use MALDI-TOF mass spectrometry for routine bacterial identification. Issues with differentiation of *S. pneumoniae* from closely related viridans species such as *S. mitis* have been observed with MALDI-TOF mass spectrometry.

Results from the *S. pneumoniae* antigen detection test in urine, in conjunction with clinical and radiologic findings, can aid diagnosis. The BinaxNOW *S. pneumoniae* antigen card (Alere, Waltham, MA) is an immunochromatographic test based on the detection of a C polysaccharide common to all *S. pneumoniae*. The test has a specificity greater than 90% and sensitivity between 50% and 80% in urine. Because of low sensitivity, less than 30%, direct antigen detection tests are not recommended on cerebrospinal fluid. The FilmArray BCID panel is a qualitative multiplexed nucleic acid-based diagnostic test that can be used for rapid identification of *S. pneumoniae* in blood culture.

Antimicrobial resistance

The susceptibility of *S. pneumoniae* to penicillin and macrolides has varied with time, geographic region, and country. Because most isolates are susceptible to penicillin when administered parenterally, penicillin remains the drug of choice for treating pneumococcal infections. Penicillin resistance is caused by altered penicillin-binding proteins. Penicillin-resistant pneumococci are reported to show resistance to other classes of drugs, such as β -lactams, macrolides, and tetracyclines. Resistance to extended-spectrum cephalosporins, such as ceftriaxone and cefotaxime, has also increased, although these agents have been used successfully in the treatment of serious infections caused by penicillin-resistant pneumococci.

Multidrug-resistant *S. pneumoniae*, defined as pneumococcal isolates resistant in vitro to two or more classes of antimicrobial agents, has been reported and can occur in the presence or absence of penicillin resistance. Pneumococcal strains that exhibit resistance to various antimicrobial agents, such as erythromycin, tetracycline, chloramphenicol, and trimethoprim-sulfamethoxazole, have emerged.

Viridans streptococci

Viridans streptococci are constituents of the normal microbiota of the upper respiratory tract, the female genital tract, and the gastrointestinal tract. The term *viridans* means "green," referring to the α -hemolysis many species exhibit. However,

β -hemolytic and nonhemolytic species are also classified as viridans streptococci. **Viridans streptococci are fastidious, with some strains requiring CO₂ for growth.**

More than 30 species are now recognized. The current classification assigns streptococcal species in the viridans group to one of five groups: (1) *S. mitis* group (including *S. mitis*, *S. pneumoniae*, *S. pseudopneumoniae*, *S. sanguinis*, and *S. oralis*); (2) *S. mutans* group (including *S. mutans* and *S. sobrinus*); (3) *S. salivarius* group (including *S. salivarius* and *S. vestibularis*); (4) *S. bovis* group (including *S. equinus*, *S. gallolyticus*, and *S. infantarius*); and (5) *S. anginosus* group (including *S. anginosus*, *S. constellatus*, and *S. intermedius*). Several species remain unclassified. Organisms of the *S. anginosus* group can possess Lancefield group A, C, F, G, or N antigen and in some instances may not be groupable. The organisms also can cross-react with other grouping antisera. Thus identification using Lancefield antisera is of little value. However, a small-colony-forming streptococcus positive for group F antigen isolated from a human specimen is likely a member of the *S. anginosus* group. The *S. salivarius* group and *S. bovis* group have some similar characteristics.

The *S. bovis* group belong to group D streptococci. The *S. bovis* group and the enterococci possess the group D antigen. *S. bovis* is no longer a valid species name. DNA studies found that *S. bovis* and *S. equinus* were the same species, and the earlier species name, *S. equinus*, was adopted. However, current methodologies have identified all human isolates of the *S. bovis* group to be *S. gallolyticus*. Until the mid-1980s, group D streptococci were subdivided into the enterococcal and nonenterococcal groups, with the understanding that organisms found in the intestinal tract were part of the enterococcal group. Both groups were bile esculin positive, but the non-enterococcal organisms would not grow in a nutrient broth with 6.5% NaCl. As more became known about the molecular characteristics of each of these subgroups, the enterococcal group was placed into a new genus, *Enterococcus*, but the non-enterococcal group remained part of group D streptococci.

Clinical infections

Viridans streptococci are oropharyngeal commensals that are regarded as opportunistic pathogens. Although their virulence is low, they cause disease if host defenses are compromised. Viridans streptococci are the most common cause of subacute bacterial endocarditis, a condition associated with a transient bacteremia. Viridans streptococcal bacteremia is more common in children than in adults and is usually more prevalent in patients with hematologic malignancies. Fatal cases have been characterized by fulminant cardiovascular collapse or meningitis. Generally, the course of endocarditis is very slow; symptoms may be present for weeks or months. Individuals whose heart valves have been damaged by rheumatic fever are especially susceptible to endocarditis from viridans streptococci.

Besides bloodstream infections, viridans streptococci play a role in oral infections such as gingivitis and dental caries (cavities). They have also been implicated in meningitis, abscesses, osteomyelitis, and empyema. Although viridans streptococci are frequently isolated in association with other bacteria from bronchial brushing, their role in bacterial pneumonia is unclear. Most viridans streptococcal infections are treated with penicillin, although some resistant strains have been reported.

Most members of the *S. anginosus* group are considered part of the normal oral and gastrointestinal microbiota; however, they have been associated with abscess formation in the oropharynx, brain, and peritoneal cavity. Members of the *S. anginosus* group have been isolated from bacteremic patients with invasive pyogenic infections with the tendency to form abscesses. *S. constellatus* subsp. *pharyngis* has been linked to pharyngitis. All clinically significant species of the *S. sanguinis* group have been isolated from patients with endocarditis.

The *S. mitis* group is normally found in the oral cavity, gastrointestinal tract, and female genital tract. Members also can be found as transient normal microbiota of the skin. Although they can be isolated from the blood of asymptomatic individuals, they are the most common isolates associated with bacterial endocarditis in native valves and, less frequently, in prosthetic valve infections. *S. salivarius* and *S. vestibularis* have been isolated from human specimens. *S. salivarius* has been linked to bacteremia, endocarditis, and meningitis, whereas *S. vestibularis* has not been associated with disease. *S. pseudopneumoniae* isolates have been observed in patients with respiratory tract infection and chronic obstructive pulmonary disease (COPD). Unlike *S. pneumoniae*, *S. pseudopneumoniae* do not have a capsule and are insoluble in bile. However, they demonstrate resistance or indeterminate susceptibility to optochin when incubated in 5% CO₂ and susceptibility to optochin when incubated in ambient air.

Among the viridans streptococci, the *S. mutans* group is the most commonly isolated, and members are usually recovered from the oral cavity. *S. mutans* is the primary contributor to dental caries. It is also the most common member of the *S. mutans* group associated with bacteremia. Members of the *S. bovis* group are often encountered in blood cultures of patients with bacteremia, septicemia, and endocarditis. The presence of *S. gallolyticus* subsp. *gallolyticus* in blood cultures has a high correlation with gastrointestinal carcinoma.

Virulence factors

Virulence factors that characterize the pathogenicity of viridans streptococci have not been well established. A polysaccharide capsule and cytolysin have been identified in some members of the *S. anginosus* group. Besides these, extracellular dextran and cell surface-associated proteins (adhesins) have been implicated in adherence and colonization of these organisms in endocarditis. Group C and G streptococci possess M proteins with similarity to those of GAS. Some of them also produce extracellular enzymes such as SLO, hyaluronidase, and DNase.

Laboratory diagnosis

It is extremely difficult to identify isolates of the viridans group to the species level; clinical laboratories should be satisfied to place isolates into one of the five groups. All members are PYR negative and **leucine aminopeptidase (LAP)** positive. Viridans streptococci show typical *Streptococcus* characteristics on Gram stain. On SBA, colonies are small and are surrounded by a zone of α -hemolysis; some isolates are β -hemolytic or nonhemolytic. The lack of β -hemolysis separates the viridans streptococci from groups A, B, C, and G. The differentiation of α -hemolytic viridans streptococci from *S. pneumoniae*, also α -hemolytic, is based on optochin sensitivity, bile solubility, or anticapsular antibody tests.

Table 15.4 Characteristics of Viridans Streptococci^a

	Mannitol	Sorbitol	Voges-Proskauer	Arginine Hydrolysis	Esculin Hydrolysis	Urease	Hemolytic Pattern

From Spellerberg, B., et al. (2019). *Streptococcus*. In K. C. Carroll, et al. (Eds.), *Manual of clinical microbiology* (12th ed., p. 399). Washington, DC: ASM Press.

The ability to ferment sugars, the Voges-Proskauer (VP) reaction, β-D-glucuronidase activity, and hippurate hydrolysis are used for the differentiation of species within the viridans group. Some commercial multitest kits can identify more commonly isolated species; however, not all species are part of the manufacturers' databases. The hemolytic patterns and some biochemical tests that distinguish members of the viridans group are shown in Table 15.4.

S. anginosus is composed of strains that may have A, C, F, G, or no Lancefield antigen. These are minute colony types showing α-hemolysis, β-hemolysis, or no hemolysis. When they are β-hemolytic, the zone size is several times the size of the colony. When they are growing in pure culture or in high concentration, a characteristic sweet odor of honeysuckle or butterscotch may be present.

Two groups that might be confused with each other are the genus *Enterococcus* and group D streptococci. Members of the *S. bovis* group express the D antigen. Both group D streptococci and enterococci are usually nonhemolytic (Fig. 15.9), although occasionally enterococcal isolates can be α-hemolytic or β-hemolytic. The differentiation of nonhemolytic streptococci is outlined in Fig. 15.10. Both enterococci and group D streptococci are bile esculin positive. Growth in 6.5% NaCl broth differentiates *Enterococcus* from viridans streptococci that fail to grow (Fig. 15.11). In addition, group D streptococci can be separated from *Enterococcus* with the PYR test; group D streptococci test negative, whereas enterococci test positive. It is important to distinguish group D streptococci from *Enterococcus* because group D streptococci are generally susceptible to penicillin, whereas *Enterococcus* organisms are usually resistant. Some strains of *S. salivarius* can be misidentified as members of the *S. bovis* group because a significant number of *S. salivarius* isolates are bile esculin positive.

Development of molecular methods such as DNA hybridization and PCR for identification of viridans streptococci has been challenging. Multilocus sequence analysis may be used to identify unknown streptococcal species. MALDI-TOF mass spectrometry microbial systems are being evaluated in clinical laboratories for identification of viridans streptococci and for rapidly distinguishing them from enterococci and *S. pneumoniae*.

Enterococcus

The enterococci consist of gram-positive cocci that are natural inhabitants of the intestinal tracts of humans and animals.

Fig. 15.9 *Enterococcus* species growing on sheep blood agar.

Fig. 15.10 Schematic diagram for identification of nonhemolytic streptococci. PYR, Pyrrolidonyl α-naphthylamide.

The commonly identified species in clinical specimens are *E. faecalis* and *E. faecium*. Other species such as *E. durans*, *E. avium*, *E. casseliflavus*, *E. gallinarum*, *E. hirae*, and *E. raffinosus* are observed occasionally. All species produce the cell wall-associated group D antigen in the Lancefield classification system.

Most enterococci are nonhemolytic or α-hemolytic, although some strains show β-hemolysis. Enterococci sometimes exhibit a pseudocatalase reaction—weak bubbling in the catalase test. Identification to the species level is based on biochemical characteristics. In contrast with streptococci, enterococci have the ability to grow under extreme conditions—for example, in the presence of bile or 6.5% NaCl or at 45°C or alkaline pH. The ability of enterococci to hydrolyze PYR is useful for differentiating them from group D streptococci (Figs. 15.10 and 15.11).

Virulence factors

The virulence factors that contribute to the pathogenicity of enterococci are incompletely understood. The enterococci have a survival advantage over other organisms in that they can grow in extreme conditions and are resistant to multiple antimicrobial agents. Extracellular surface adhesin proteins, extracellular serine protease, and gelatinase of *E. faecalis* are thought to play a role in the colonization of the species and adherence to heart valves and renal epithelial cells. *E. faecalis* also produces a two-subunit toxin, termed *cytolysin*. This toxin shows similarity to bacteriocins produced by other gram-positive bacteria and is expressed by a quorum-sensing mechanism.

Clinical infections

Enterococci are frequent causes of healthcare-associated infections and have been associated with increased use of third-generation cephalosporins to which they are intrinsically resistant. Healthcare-associated UTIs are the most

common, followed by bacteremia. UTI is often associated with urinary catheterization or other urologic manipulations. Prolonged hospitalization is a risk factor for acquiring enterococcal bacteremia. Bacteremia is often observed in patients receiving hemodialysis, immunocompromised patients with a serious underlying disease, or patients who have undergone a prior surgical procedure. Endocarditis from enterococci is seen mainly in older adult patients with prosthetic valves or valvular heart disease. Enterococci account for about 5% to 10% of infections in patients with bacterial endocarditis.

Although they are frequently isolated from intraabdominal or pelvic wound infections, their role in these infections remains contentious. In burn patients, enterococcal wound infection and sepsis resulting from contaminated xenografts have been reported. Rare cases of enterococcal infection of the central nervous system in patients who have had neurosurgery or head trauma and in immunosuppressed patients with enterococcal bacteremia have been reported. Respiratory tract infections from enterococci are also rare and have been reported in severely ill patients who have had prolonged antimicrobial therapy.

Laboratory diagnosis

Standard procedures for collection and transport of blood, urine, or wound specimens should be followed. The specimens should be cultured as soon as possible with minimum delay. Trypticase soy or brain-heart infusion agar supplemented with 5% sheep blood is routinely used to culture enterococci. Enterococci grow well at 35° C in the presence of CO₂ but do not require a high level of CO₂ for growth. If the clinical specimen is obtained from a contaminated site or is likely to contain gram-negative organisms, selective media containing bile esculin azide, colistin–nalidixic acid, phenylethyl alcohol, cephalexin–aztreonam–arabinose, or chromogenic substrates should be used for isolation of enterococci.

Enterococcus spp. are identified based on several biochemical characteristics. *E. faecalis* is easily identified by its ability to grow in the presence of tellurite, as shown in Table 15.5. Commercially available multitest kits may be useful for identification of *E. faecalis*, but they are inadequate for other enterococci. Molecular typing methods, such as pulsed-field gel electrophoresis, contour-clamped homogeneous electric-field electrophoresis, ribotyping, PCR-based typing methods, and whole-genome sequencing, have been used mainly to type

Enterococcus spp. in epidemiologic studies and investigations of vancomycin-resistant enterococci (VRE).

Antimicrobial resistance

Enterococcus spp. show resistance to several commonly used antimicrobial agents; therefore differentiation from *Streptococcus* and susceptibility testing are important. Enterococci have intrinsic or acquired resistance to several antimicrobial agents, including aminoglycosides, β -lactams, and glycopeptides. Because of their low expression of penicillin-binding proteins, *Enterococcus* spp. are resistant to β -lactams. Resistance of enterococci to glycopeptides such as vancomycin and teicoplanin was first described in the late 1980s. Nine vancomycin-resistant phenotypes have been described in enterococci: VanA, VanB, VanC, VanD, VanE, VanG, VanL, VanM, and VanN. The phenotypes VanA, VanB, VanD, and VanM replace the D-Ala-D-Ala termini of peptidoglycan pentapeptide precursors with D-Ala-D-lactate. The phenotypes VanC, VanE, VanG, VanL, and VanN replace the peptidoglycan pentapeptide precursors termini with D-Ala-D-Ser. The VanC phenotype was first observed in *E. gallinarum* and *E. casseliflavus*, which are intrinsically resistant to vancomycin. Of the vancomycin-resistant phenotypes, VanA and VanB phenotypes are most frequently encountered. The VanA phenotype is inducible, carried on a transposon (Tn1546) in the chromosome or plasmid, and characterized by high-level resistance to vancomycin (MIC $>32\mu\text{g/mL}$) and teicoplanin (MIC $>16\mu\text{g/mL}$), whereas the VanB phenotype is also inducible and carried on a transposon Tn5382 (previously Tn1549) in the chromosome or plasmid and characterized by variable levels of resistance to vancomycin and susceptibility to teicoplanin.

VRE is a global problem. *E. faecium* is responsible for the majority of the VRE infections. In the United States, approximately 14% of *E. faecalis* and 87% of *E. faecium* isolated from blood are vancomycin resistant. The frequency of VRE isolates in regions outside the United States range from 14% to 48%. Vancomycin-containing agar and chromogenic VRE media have been used for screening of VRE colonization and for infection control in hospitals. In addition, PCR-based assays have been used to detect VRE.

Streptococcus-like organisms

The genera *Aerococcus*, *Gemella*, *Lactococcus*, *Leuconostoc*, and *Pediococcus* consist of organisms that resemble viridans streptococci. These bacteria have been isolated in clinical specimens and are associated with infections similar to those caused by enterococci and streptococci. These organisms are frequently identified when antimicrobial susceptibility testing of a "streptococcal" isolate reveals it to be vancomycin resistant. The vancomycin-resistant, gram-positive cocci are likely to be *Leuconostoc* or *Pediococcus*. *Aerococcus* is normally susceptible to vancomycin.

Abiotrophia and Granulicatella

Abiotrophia and *Granulicatella* spp., formerly known as the *nutritionally variant streptococci*, were first described in 1961. These bacteria grow as satellite colonies around other bacteria and require sulfhydryl compounds for growth. These organisms are part of the human oral and gastrointestinal microbiota. Most of the species are not groupable by the Lancefield system;

however, strains with group antigens A, F, H, L, and N have been reported. *Abiotrophia* and *Granulicatella* spp. are phenotypically related to members of the genera *Facklamia*, *Ignavigranum*, *Globicatella*, *Eremococcus*, *Dolosicoccus*, and *Aerococcus*.

Abiotrophia and *Granulicatella* spp. are a significant cause of bacteremia, endocarditis, and otitis media. *Granulicatella adiacens*, *Granulicatella elegans*, and *Granulicatella balaenopterae* have been isolated from blood cultures and tissue samples. Endocarditis resulting from these organisms is difficult to treat because of the increased tolerance of the organisms to antimicrobial agents. Surgery is usually required to achieve a cure. *Abiotrophia* and *Granulicatella* spp. have been linked to a few cases of osteomyelitis, endophthalmitis after cataract extraction, brain abscess, chronic sinusitis, septic arthritis, meningitis, and breast implant-associated infections.

Infection with *Abiotrophia* and *Granulicatella* spp. should be suspected when gram-positive cocci resembling streptococci are observed in positive blood cultures that subsequently fail to grow on subculture. It would be appropriate to use an SBA plate with a *S. aureus* streak and examine it for satellitism. Alternatively, media can be supplemented with 10 mg/L pyridoxal hydrochloride. *Granulicatella* spp. are often misdiagnosed and require a combination of approaches for identification. Tests for the production of β -glucuronidase, hippurate hydrolysis, arginine dihydrolase activity, and acid production from trehalose, sucrose, pullulan, and tagatose are used to differentiate the *Abiotrophia* and *Granulicatella* spp.

Aerococcus

Aerococcus is a common airborne organism that belongs to the family Aerococcaceae. It is a widespread, opportunistic pathogen causing an increasing number of infections associated with bacteremia, endocarditis, and UTI in immunocompromised patients. *Aerococcus viridans* has been linked to cases of bacteremia and endocarditis. *Aerococcus urinae* and *Aerococcus sanguinicola* have been associated with invasive diseases, such as sepsis, endocarditis, lymphadenitis, and peritonitis, often originating from the urinary tract. UTIs are seen more often in older adult women. However, invasive infections occur most frequently in older adult men, but the outcome is generally favorable. Both species are known to aggregate platelets and form biofilms.

Aerococcus resemble viridans streptococci on culture but are microscopically similar to staphylococci in that they occur as tetrads or clusters. These organisms sometimes show a weak catalase or pseudocatalase reaction. They grow in the presence of 6.5% NaCl and can easily be confused with enterococci. Their susceptibility pattern can also resemble that of the enterococci. Some strains of *A. viridans* are bile esculin positive and PYR positive. *A. urinae* is bile esculin negative and PYR negative. Because of their similarity to the staphylococci, streptococci, and enterococci, they are often difficult to accurately identify. However, 16S ribosomal ribonucleic acid (rRNA) sequencing and MALDI-TOF mass spectrometry testing seem to accurately identify *A. urinae*, *A. sanguinicola*, and *A. viridans*.

Dolosicoccus and Globicatella

Dolosicoccus and *Globicatella* are minor genera in the family Aerococcaceae. *D. paucivoran*, the single species in the genus, has been isolated in blood specimens. *D. paucivoran* can be

differentiated from *Globicatella* spp. based on biochemical and molecular tests.

Globicatella spp. were first described in 1992 and isolated from blood, urine, and CSF in patients with bacteremia, UTI, and meningitis. These facultative anaerobic, catalase-negative, α -hemolytic, gram-positive cocci are rarely isolated in clinical laboratories and often misidentified. The only species identified in human infection is *G. sanguinis*.

Dolosigranulum

Dolosigranulum spp. were first described in 1993 and are facultatively anaerobic, non motile cocci that occur in pairs, tetrads, or clusters. One species, *Dolosigranulum pigrum*, has been associated with eye infections, sepsis, healthcare-associated pneumonia, and ventilator-associated pneumonia in immunocompromised patients and patients with cystic fibrosis and COPD.

Facklamia

Facklamia species are α -hemolytic, catalase-negative, facultative anaerobic cocci seen in pairs or chains and have been misidentified as viridans streptococci. The species *F. hominis*, *F. ignava*, *F. sourekkii*, and *F. languida* have been isolated in human clinical specimens in patients with infective endocarditis and bacteremia.

Gemella

Gemella spp. are similar in colony morphology and habitat to viridans streptococci; they produce α -hemolysis or are nonhemolytic. The bacteria easily decolorize on Gram staining and often appear as gram-negative cocci in pairs, tetrads, clusters, or short chains. *Gemella* spp. have been isolated from cases of endocarditis, wounds, and abscesses. The most significant species is *Gemella haemolysans*.

Lactococcus

Lactococcus spp. are gram-positive cocci that occur singly, in pairs, or in chains and are physiologically similar to enterococci. On SBA, these organisms produce α -hemolysis or are nonhemolytic. These organisms were previously classified as group N streptococci. *Lactococcus* spp. have been isolated from patients with UTI and endocarditis. Production of acid from carbohydrates is useful in distinguishing *Lactococcus* spp. from enterococci. Also, these microorganisms do not react with the genetic probe in the AccuProbe *Enterococcus* culture confirmation test (Gen-Probe, San Diego, CA).

Leuconostoc

The genus *Leuconostoc* consists of catalase-negative, gram-positive microorganisms with irregular coccoid morphology (Fig. 15.12). These organisms share several phenotypic and biochemical characteristics with *Lactobacillus* spp., viridans streptococci (Fig. 15.13), *Pediococcus* spp., and *Enterococcus* spp. and are sometimes misidentified. Some species cross-react with the Lancefield group D antiserum. These microorganisms are intrinsically resistant to vancomycin. In nature, they are frequently found on plant surfaces and vegetables, and in milk products. They are recognized as opportunistic pathogens in

Fig. 15.12 Gram stain of *Leuconostoc* species ($\times 1000$).

Fig. 15.13 Colonies of *Leuconostoc* species growing on sheep blood agar. *Leuconostoc* spp. may produce α -hemolysis and can resemble viridans streptococci.

patients who are immunocompromised or treated for underlying disease with vancomycin. These microorganisms have been isolated from cases of meningitis, bacteremia, UTIs, and pulmonary infections. Species associated with infection include *Leuconostoc citreum*, *Leuconostoc cremoris*, *Leuconostoc dextranicum*, *Leuconostoc lactis*, *Leuconostoc mesenteroides*, and *Leuconostoc pseudomesenteroides*. Biochemical identification is based on the absence of catalase, PYR, and LAP activities; hydrolysis of esculin in the presence of bile; growth in the presence of 6.5% NaCl; and production of gas from glucose.

Pediococcus

Members of the genus *Pediococcus* are facultatively anaerobic, gram-positive cocci (arranged in pairs, tetrads, and clusters) that can grow at 45° C. They may be misidentified as viridans streptococci or enterococci. Similar to *Leuconostoc* spp., *Pediococcus* spp. (*P. acidilactici*, *P. damnosus*, *P. dextrinicus*, *P. parvulus*, and *P. pentasaceus*) are intrinsically resistant to vancomycin. *Pediococcus* spp. have been associated with infections in patients who have underlying gastrointestinal abnormalities or who have previously undergone abdominal surgery. The organisms have also been linked to bacteremia, abscess

formation, and meningitis. Biochemical characteristics used to identify them include a positive bile esculin test, the presence of LAP activity, and absence of PYR activity. The organisms do not produce gas from glucose. Some of the strains are able to grow in the presence of 6.5% NaCl.

Vagococcus

Vagococcus spp. are commonly found in animals including pigs, cattle, horses, and cats. They are uncommonly found in humans but have been isolated from blood, cerebrospinal fluid, and wounds. The most common human isolate is *Vagococcus fluvialis*. Isolates typically express the Lancefield N antigen similar to *Lactococcus* and are difficult to identify and differentiate from *Enterococcus* spp. by conventional methods. *Vagococcus* spp. are facultative anaerobic, catalase-negative, motile, gram-positive cocci. MALDI-TOF mass spectrometry or 16s rRNA are the best methods for identification.

Laboratory diagnosis

Classification schemes

Several different approaches to the classification of catalase-negative, gram-positive cocci have been used. Four commonly used classification schemes are (1) hemolytic pattern on SBA; (2) physiologic characteristics; (3) serologic grouping or typing of C carbohydrate (Lancefield classification), capsular polysaccharide, or surface protein, such as the M protein of *S. pyogenes*; and (4) biochemical characteristics. The identification process for a streptococcal isolate in the clinical laboratory may use features from each scheme. More recently, MALDI-TOF mass spectrometry and genetic probes and sequencing have been used.

Hemolytic patterns

The medical laboratory scientist often makes an initial classification of the streptococci based on the hemolytic pattern of the isolate grown on SBA. Although hemolytic patterns can be helpful during the initial workup of an isolate, many species of streptococci show variable hemolytic patterns. The types of hemolysis possible are outlined in [Table 15.1](#).

Physiologic characteristics

The classification based on physiologic characteristics divides the streptococcal species into four groups: pyogenic streptococci, lactococci, enterococci, and viridans streptococci. Pyogenic streptococci produce pus; these organisms are mostly β -hemolytic and constitute most of the Lancefield groups. The lactococci are nonhemolytic organisms with a Lancefield group N antigen and are often found in dairy products. Enterococci comprise species found as part of the normal biota of the human intestine. Viridans streptococci are widely found as normal biota in the upper respiratory tract of humans. Most strains lack a C carbohydrate and are not part of the Lancefield classification; however, some have A, C, F, G, or N antigen. The viridans streptococci are α -hemolytic or nonhemolytic and are often seen as opportunistic pathogens. For the most part, this physiologic classification is historical.

Nevertheless, the terms *enterococci* and *viridans streptococci* remain and are still used to describe clinical isolates.

Lancefield classification scheme

Because of readily available commercial kits, the **Lancefield classification system** is the most commonly used scheme. The classification system is based on extraction of C carbohydrate from the streptococcal cell wall by placing the organisms in dilute acid and heating for 10 minutes. The soluble antigen is used to immunize rabbits to obtain antisera to the various C carbohydrate groups. The Lancefield serologic grouping has been most significant in classifying and identifying β -hemolytic streptococci. However, because DNA relatedness has been applied to the classification and identification of α -hemolytic streptococcal species during the past several decades, investigators have found no correlation between genetic relationships and streptococcal group antigens. In contrast with group B β -hemolytic streptococci, in which only one species is identified, α -hemolytic streptococci as a whole are phenotypically and genotypically diverse and difficult to characterize.

The C carbohydrate is also present in streptococcal species other than those that produce β -hemolysis. Some are found as normal biota in animals or as animal pathogens, and others may be found in both humans and animals. These species belong to Lancefield groups A, B, C, D, F, G, and N, although not all members of these groups cause human infection. The classification of *Streptococcus* and *Enterococcus* spp. is shown in [Table 15.2](#).

Biochemical identification

Biochemical identification can be performed even by small laboratories. Although definitive identification requires a large number of biochemical characteristics or perhaps serologic methods, presumptive identification can be accomplished easily with a few key tests and characteristics ([Fig. 15.14](#)). Initial biochemical tests performed are often selected based on the hemolytic reaction of the isolate. In most cases, presumptive identification possesses a high enough rate of accuracy to be useful to the clinician and does not require the exhaustive additional tests that are needed to meet the criteria for definitive identification, especially for species in groups A, B, and D as well as *S. pneumoniae* and *Enterococcus* spp. However, speciation of the viridans streptococci does require a considerable increase in the number of tests.

The biochemical tests used for identification of streptococci include (1) bacitracin susceptibility, (2) the CAMP test, (3) hippurate hydrolysis, (4) PYR hydrolysis, (5) LAP, (6) VP, (7) β -D-glucuronidase, (8) bile esculin and salt tolerance, (9) optochin susceptibility, and (10) bile solubility tests. [Table 15.3](#) outlines the biochemical characteristics used for presumptive identification of selected members of the family Streptococcaceae and similar organisms. Several multitest commercial kits are available, such as the RapID STR (Thermo Fisher Scientific) shown in [Fig. 15.15](#). Some clinical laboratories forego biochemical testing and identify streptococci by detection of the group antigen. In selecting an identification scheme or kit, the medical laboratory scientist must evaluate the needs of the clinicians and patient population served, the cost of an expanded identification

^aRare isolates of enterococci are β -hemolytic. Enterococci are PYR positive and resistant to bacitracin.

^bPerform additional tests if isolate is from nonrespiratory source.

Fig. 15.14 Schematic diagram for the presumptive identification of gram-positive cocci. PYR, Pyrrolidonyl α -naphthylamide; R, resistant; S, susceptible.

scheme, the resources and abilities of the laboratory, and the usefulness of the data obtained. The procedures for many of the following tests can be found in [Appendix D](#) on Evolve.

Bacitracin susceptibility

Historically, bacitracin susceptibility has been used as an inexpensive test for presumptive identification of *S. pyogenes*. This method is helpful in screening for GAS in throat cultures. The throat swab is used to inoculate SBA containing SMZ, and a bacitracin disk is placed directly onto the agar. Growth of most interfering respiratory microbiota is inhibited by SMZ, but *S. pyogenes* and *S. agalactiae* grow. β -Hemolytic colonies that grow and are susceptible to bacitracin are presumptively identified as *S. pyogenes* (Fig. 15.16). *S. pyogenes* (group A) is susceptible to bacitracin and resistant to SMZ, whereas *S. agalactiae* (group B) is resistant to both bacitracin and SMZ. The PYR test, discussed later, is a more specific rapid test for GAS.

CAMP test

The **CAMP test** is used for presumptive identification of GBS. CAMP is an acronym derived from the first letters of the surnames of the individuals who first described the reaction: Christie, Atkins, and Munch-Petersen. The CAMP test can be performed in three ways. One is with the use of a β -lysin-producing strain of *S. aureus*; another is with the use of a disk impregnated with the β -lysin. Both methods take advantage

of the enhanced hemolysis occurring when the β -lysin and the hemolysin produced by GBS are in contact. *S. aureus* is inoculated in a straight line in the center of an SBA plate. The unknown streptococcal isolate is inoculated perpendicularly to the *S. aureus* inoculum. The result is a characteristic arrowhead-shaped hemolytic pattern (Fig. 15.17). When a disk containing β -lysin is used, the enhanced hemolysis is not a typical arrowhead shape because the disk is round. A third method, the rapid CAMP test (or spot CAMP test), involves placing a drop of extracted β -lysin on the area of confluent growth of the suspected GBS. After incubation at 35°C for at least 20 minutes, enhanced hemolysis is observed (Fig. 15.18).

Hippurate hydrolysis

A useful test for differentiating *S. agalactiae* from other β -hemolytic streptococci is the **hippurate hydrolysis test**. *S. agalactiae* possesses the enzyme hippuricase (also called *hippurate hydrolase*), which hydrolyzes sodium hippurate to form sodium benzoate and glycine. A 2-hour rapid test is available to detect the presence of hippurate hydrolase.

Pyrrolidonyl- α -naphthylamide hydrolysis

The PYR hydrolysis test detects the activity of L-pyrrolidonyl arylamidase, also called *pyrrolidonyl aminopeptidase*. *S. pyogenes* is the only species of *Streptococcus* that is PYR positive. Other genera that are PYR positive include *Enterococcus*, *Aerococcus*, and

RapID STR Color Guide

Test	Cavity	Positive Reactions	Negative Reactions	Comments
ARG	1	 	 	Without the addition of any reagents, read cavities 1-10 and record results: Cavity 1: Development of a red or dark orange color is a positive test; a yellow or yellow-orange color is a negative test.
ESC	2		  	Cavity 2: Development of a black color is a positive test; a clear, tan, or a light brown color is a negative test.
MNL	3			
SBL	4	 	 	Cavities 3-5: Development of a yellow or yellow-orange color is a positive test; a red or orange color is a negative test.
RAF	5			
INU	6	 		Cavity 6: Development of a yellow or orange color is a positive test; a red color is a negative test.
GAL	7			
GLU	8		 	Cavities 7-10: Development of a significant yellow color is a positive test; a very pale or clear color is a negative test.
NAG	9			
PO4	10			
TYR	7	 	  	Cavities 7-8: Development of a purple color, without regard to intensity, is a positive test; a clear, tan, or yellow color is a negative test.
HPR	8			
LYS	9	 	  	Cavities 9-10: Development of a very dark purple color is a positive test; a light to medium purple color is a negative test.
PYR	10			

Note: The RapID Color Guides are intended as an educational aid to be used in conjunction with the Technical Insert for the product. The reaction colors shown in the charts represent the typical shades of positive and negative colors.

800-447-3641 or 800-225-5443
(Technical Service)

PRINTED IN U.S.A. 3/98

Fig. 15.15 RapID STR panel for the identification of *Streptococcus* spp. **A**, Commercial test well cartridge containing various substrates. **B**, Interpretive color guide to reactions. (Courtesy Thermo Fisher Scientific, Waltham, MA.)

Gemella. The PYR test takes advantage of the fact that *S. pyogenes* and *Enterococcus* spp. are able to hydrolyze the substrate PYR (Fig. 15.19). Several commercial systems are available. The specificity of this test for *Enterococcus* spp. is similar to that of the bile esculin and salt tolerance tests (see later). The PYR test is more specific for *S. pyogenes* than bacitracin susceptibility.

Leucine aminopeptidase

LAP is a peptidase that hydrolyzes peptide bonds adjacent to a free amino group. Because LAP reacts most quickly with leucine, it is called *leucine aminopeptidase*. The substrate, leucine- β -naphthylamide, is hydrolyzed to β -naphthylamine. After the addition of *p*-dimethylaminocinnamaldehyde reagent, a red color develops. Rapid commercial tests that use filter paper disks impregnated with the substrate are available. The LAP test is often used with the PYR test and is most

helpful in differentiating *Aerococcus* and *Leuconostoc* spp. from other gram-positive cocci. *Streptococcus*, *Enterococcus*, and *Pediococcus* spp. are LAP positive, and *Aerococcus* and *Leuconostoc* spp. are LAP negative.

Voges-Proskauer test

The **Voges-Proskauer (VP) test** is used to distinguish the small-colony-forming β -hemolytic anginosus group containing group A or C antigens from large-colony-forming pyogenic strains with the same antigens. Members of the anginosus group are positive. The VP test detects acetoin production from glucose. In the modified VP test, a heavy suspension of bacteria is made in 2 mL of VP broth. After about 6 hours of incubation at 35° C, a few drops of 5% α -naphthol and 40% potassium hydroxide are added. The tube is shaken vigorously to increase the concentration of dissolved oxygen,

and the broth is incubated at room temperature for 30 minutes. The formation of a red or pink color is a positive reaction.

β -D-glucuronidase

The β -D-glucuronidase test detects the action of β -D-glucuronidase, an enzyme found in isolates of large-colony-forming β -hemolytic group C and G streptococci but not in the small-colony-forming β -hemolytic *S. anginosus* group. Several commercially prepared rapid assays are available. A fluorogenic assay using methylumbelliferyl- β -D-glucuronide has also been described.

Bile esculin and salt tolerance

The bile esculin hydrolysis test and the salt tolerance test have been mainstays in identification schemes for nonhemolytic, catalase-negative, gram-positive cocci. The bile esculin test is a two-step test detecting growth of bacteria in the presence of 40% bile and the ability to hydrolyze esculin. Group D streptococci and *Enterococcus* spp. test positive (Fig. 15.20). Organisms positive for bile esculin are separated into group D streptococci or *Enterococcus* by the salt tolerance test. Growth in 6.5% NaCl broth is used to identify *Enterococcus* and *Aerococcus* organisms. Some species of *Pediococcus* and *Leuconostoc* grow in 6.5% NaCl broth when incubated for 24 hours. However, group D streptococci do not grow in a 6.5% NaCl broth.

Optochin susceptibility

In the **optochin test**, a filter paper disk containing optochin (ethylhydrocuprein hydrochloride) is added to the surface of an SBA plate that has just been inoculated with an α -hemolytic *Streptococcus*. The plate is incubated overnight at 35° C in a CO₂ incubator. A zone of inhibition greater than 14 mm with a 6-mm disk or a zone of inhibition greater than 16 mm with a 10-mm disk is considered susceptible and a presumptive identification of *S. pneumoniae* (Fig. 15.21). Isolates producing smaller zones should be tested for bile solubility to confirm their identity.

Bile solubility

The **bile solubility** test correlates well with optochin susceptibility. The test for bile solubility takes advantage of the *S. pneumoniae* autocatalytic enzyme amidase. Under the influence of a bile salt or detergent, the organism's cell wall lyses during cell division. A suspension of *S. pneumoniae* in a solution of sodium deoxycholate lyses, and the solution becomes clear. Other α -hemolytic organisms do not undergo autolysis, and the solution remains cloudy. Suspensions of bacteria made in saline serve as negative controls.

Noncultural identification

Immunoassays

Identification of streptococci, particularly GAS, can be accomplished by the detection of the group-specific antigen from either isolated colonies or, in some cases, a direct clinical specimen such as a throat swab. Isolated colonies can be identified by extracting the C carbohydrate by means of acid or heat. The extract containing the specific group carbohydrate is used in a capillary precipitin test or a slide agglutination test. In the capillary precipitin test, antiserum to the specific group carbohydrate is overlaid with the solution containing the streptococcal extract. After 5 to 10 minutes, the interface between the extraction solution and the antiserum is examined carefully for a white precipitate, which indicates a positive reaction. Each extract can be tested with numerous antisera specific to the various group antigens.

Fig. 15.21 Optochin susceptibility test on sheep blood agar. *Left*, *Streptococcus pneumoniae* showing susceptibility to optochin. *Right*, Resistant viridans streptococci.

An alternative method that is easier to perform is the slide agglutination test, which uses a carrier particle, such as latex, for the group-specific antibody. When an antibody-antigen reaction occurs, it is seen macroscopically as agglutination of the particles (Fig. 15.22). These immunoassays provide a definitive identification of the Lancefield group to which the isolate belongs; however, when the group comprises several species, the methods do not give a species identification. If the results indicate that the isolate belongs to group B, it can be identified as *S. agalactiae*. The cost of these methods is higher than that of the standard culture approaches; however, the results are often obtained more quickly and are often more accurate.

More than two dozen different antigen-detection products are commercially available, many of which use latex agglutination, an optical immunoassay, or an enzyme-linked immunosorbent assay system to detect GAS from throat swabs. These are designed primarily for use in a clinic or physician's office. Although a positive finding allows the primary care provider to treat *S. pyogenes* infections without waiting for culture results, a negative result in children or adolescents necessitates a throat culture because the sensitivity of direct detection methods for GAS is not high enough to ensure that the negative result is not a false-negative. The positive predictive value in adult populations is low. Additionally, the cost of using direct detection methods can be significantly higher than that of culture only. The direct detection method for GAS can be a valuable diagnostic tool in the right context; however, the cost and sensitivity must be weighed carefully.

Nucleic acid probes

Nucleic acid probe assays are commercially available and offer rapid results and increased specificity compared with conventional identification methods. However, nucleic acid probe assays cost more. The LightCycler (Roche Applied Science, Indianapolis, IN) is a real-time PCR instrument that can identify GAS and GBS as well as groups C and G. The assay detects the *cfb* gene, which encodes the CAMP-factor protein of GBS and the *ptsI* (phosphotransferase) gene of GAS. Groups C and G have a *ptsI* gene sequence similar to that of GAS, but the instrument is able to distinguish among the three

Fig. 15.22 Slide agglutination test for grouping streptococci.

groups. Compared with bacterial throat cultures for GAS, the LightCycler has a sensitivity of 93% and a specificity of 98%.

The AccuProbe pneumococcus test (Gen-Probe, San Diego, CA) uses a DNA probe to detect the 16S rRNA sequence of *S. pneumoniae*. The less than 1% difference in the rRNA sequence between *S. pneumoniae* and *S. oralis* and *S. mitis* raises questions about the specificity of this assay. The Smart Cycler (Cepheid, Sunnyvale, CA) real-time PCR instrument also provides kits for the detection of streptococci. This instrument has four-channel optics, allowing the detection of several targets in one sample (multiplex).

Susceptibility testing

Antimicrobial susceptibility testing for pathogens is used to guide therapy and identify resistance of the pathogen to antimicrobial agents used for therapy. In the case of *S. pneumoniae* and other streptococci, the Clinical and Laboratory Standards Institute (CLSI) has established procedures for both disk diffusion and broth dilution assays. Commercial methods including the Etest (AB Biodisk, Solna, Sweden) are also available. Elevated MICs may be observed with the Etest for some antimicrobial agents, possibly resulting from CO₂ incubation conditions. Testing can also be performed using automated instruments such as the BD Phoenix (Becton Dickinson, Franklin Lakes, NJ), MicroScan (Siemens Healthcare Diagnostics, Tarrytown, NY), and Vitek (bioMérieux) systems.

Penicillin remains the drug of choice in treating most streptococcal infections. However, penicillin-resistant *S. pneumoniae* and viridans group isolates have been reported worldwide, and the incidence of penicillin-resistant *S. pneumoniae* seems to be increasing. Resistance of *S. pneumoniae* to penicillin and other β -lactams occurs by alteration in the cell wall penicillin-binding proteins. Although pneumococcal resistance to β -lactams is common, high-dose parenteral penicillin G and many other parenteral and oral β -lactams have been effective in treatment. The current penicillin susceptibility breakpoint of 2 mg/mL for pneumococcal infection and 0.06 mg/mL for meningitis was published by the CLSI based on microbiological, pharmacokinetic/pharmacodynamic, and clinical information. Erythromycin and narrow-spectrum cephalosporins are alternatives, although erythromycin resistance encoded by the *erm* and *mef* genes has been reported. Multidrug-resistant pneumococci have also been reported.

Vancomycin is an effective antimicrobial for treating infections caused by gram-positive organisms. Gram-positive isolates are often routinely tested for vancomycin susceptibility. Table 15.3 lists the usual patterns of vancomycin susceptibility for many gram-positive cocci. In particular, *Pedococcus* and *Leuconostoc* are resistant to vancomycin. *E. faecalis* and *E. faecium* have emerged as therapeutically challenging organisms because of increasing resistance to vancomycin and penicillin. More recently, these VRE isolates also have a high level of resistance to aminoglycosides. The combination of an aminoglycoside with a cell wall-active agent, such as ampicillin, penicillin, or vancomycin, is often required for the treatment of enterococcal infection. The combination is effective in the absence of high-level aminoglycoside resistance. The CLSI recommends screening of enterococci isolated from blood cultures or specimens such as heart valve tissue for high-level aminoglycoside resistance with both gentamicin and streptomycin. Real-time PCR assays, such as the BD GeneOhm VanR

(BD Diagnostic Systems) and Xpert vanA/vanB (Cepheid) assays, can be used for rapid detection of VRE carrying the *vanA* and *vanB* genes from rectal and perianal swabs.

POINTS TO REMEMBER

- The organisms included in the family Streptococcaceae and the *Streptococcus*-like organisms are catalase-negative, gram-positive cocci usually arranged in pairs or chains.
- Hemolysis on SBA is often a starting point for the identification of streptococci and similar organisms.
- Many streptococci can be categorized based on Lancefield group antigens.
- Key tests for the identification of streptococci and similar organisms include bacitracin susceptibility, CAMP, hippurate hydrolysis, pyrrolidonyl- α -naphthylamide (PYR) hydrolysis, leucine aminopeptidase (LAP), Voges-Proskauer (VP), β -D-glucuronidase, bile esculin, salt tolerance, optochin susceptibility, and bile solubility tests.
- Many clinical microbiology laboratories use group antigen detection to identify the streptococci.
- Group A streptococci are important pathogens that cause acute bacterial pharyngitis, skin and soft tissue infections, and invasive infections, including necrotizing fasciitis.
- Emerging resistance of *Streptococcus pneumoniae* to numerous antimicrobials is becoming a major health concern.
- Viridans streptococci, although usually nonpathogenic, can cause bacteremias, abscesses, and oral infections such as gingivitis and dental caries.
- Nutritionally variant streptococci are classified within the genera *Granulicatella* and *Abiotrophia*.
- Enterococci cause approximately 5% to 10% of infections in patients with bacterial endocarditis.
- *Streptococcus agalactiae* is a significant cause of invasive disease in newborns.
- Group C and G streptococci are important human pathogens associated with infections such as endocarditis, meningitis, primary bacteremia, necrotizing fasciitis, and myositis.

LEARNING ASSESSMENT QUESTIONS

1. Name three tests that could be performed to aid in the identification of *Streptococcus pyogenes*.
2. A β -hemolytic, catalase-negative, gram-positive coccus is found to be resistant to bacitracin and sulfamethoxazole. Which of the following is a likely presumptive identification?
 - a. Group A streptococci
 - b. Group B streptococci
 - c. Group D streptococci
 - d. Enterococci
3. The Christie, Atkins, Munch-Petersen (CAMP) test is based on enhanced hemolysis between CAMP factor and β -lysin from which of the following?
 - a. *Streptococcus agalactiae*
 - b. *Staphylococcus epidermidis*
 - c. *Staphylococcus aureus*
 - d. *Enterococcus*

4. A nonhemolytic, catalase-negative, gram-positive coccus is pyrrolidonyl α -naphthylamide (PYR) positive. You should also expect the isolate to have which of the following characteristics?
 - a. Bile esculin positive
 - b. Salt (6.5%) tolerant
 - c. Bile soluble
 - d. Both a and b
5. The optochin test is most valuable in the identification of which of the following?
 - a. α -Hemolytic streptococci
 - b. β -Hemolytic streptococci
 - c. Nonhemolytic streptococci
 - d. Both a and b
6. Which antimicrobial agent or agents are most commonly used to treat infections caused by pyogenic streptococci?
7. *Streptococcus pyogenes* has been associated with which invasive infections?
8. Which streptococcal species is the most common cause of community-acquired bacterial pneumonia?
9. What is the clinical significance of group B streptococci isolated from a vaginal culture of a pregnant woman?
10. How would you recover nutritionally variant streptococci from clinical samples such as blood?
11. A 9-year-old boy complains of fever, severe headache, and sore throat. On examination, his pharynx is red, and his tonsils are swollen. The throat culture grows β -hemolytic colonies on sheep blood agar and is identified as group A streptococci. Which two serious complications can result if the infection is not treated (post-infection sequelae)?
12. You isolated α -hemolytic colonies from the sputum sample of a 75-year-old patient. When tested, the colonies were found to be catalase negative, optochin (P disk) resistant, bile solubility test negative, and bile esculin test negative. This isolate can be identified as which of the following?
 - a. *Streptococcus agalactiae*
 - b. Viridans streptococci
 - c. *Streptococcus pneumoniae*
 - d. *Enterococcus faecalis*
13. A cerebrospinal fluid sample from a neonate grows gram-positive cocci that are β -hemolytic and catalase negative. Which of the following group of tests would be most helpful in identifying the organism?
 - a. Bacitracin, CAMP, and hippurate hydrolysis
 - b. Optochin, CAMP, and bile solubility
 - c. Growth in 6.5% NaCl and bile esculin
 - d. Gram stain and motility
14. Which of the following organisms would be best described as a gram-positive coccus that is a normal colonizer of the gastrointestinal (GI) tract that enters the bloodstream causing bacteremia and is thought to be closely associated with GI disorders including colon cancer?
 - a. Group B streptococci
 - b. Viridans streptococci
 - c. Group D streptococci
 - d. *Staphylococcus aureus*
15. Streptolysin S and streptolysin O are virulence factors produced by which of the following organisms?
 - a. Group B streptococci
 - b. Viridans streptococci
 - c. Group D streptococci
 - d. *Streptococcus pyogenes*

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Compare the general characteristics of the aerobic gram-positive bacilli discussed in this chapter.
2. Compare the clinical significance of the aerobic gram-positive bacilli and how the infections they cause are acquired.
3. Describe the types of clinical specimens that are likely to contain the aerobic gram-positive bacilli discussed in this chapter.
4. Describe the microscopic morphology and colony appearance of the aerobic gram-positive bacilli discussed in this chapter.
5. Describe the clinical infections associated with *Corynebacterium diphtheriae*.
6. Justify the use of in vitro diphtheria exotoxin detection by *C. diphtheriae*.
7. Discuss several nondiphtheria *Corynebacterium* spp. that are capable of causing clinical infection in humans.

8. Compare the culture and identifying characteristics of *Listeria monocytogenes* with *Streptococcus agalactiae* (group B streptococci).
9. Differentiate *L. monocytogenes* from other non-spore-forming gram-positive bacilli and streptococci.
10. Differentiate *Erysipelothrix rhusiopathiae* from other non-spore-forming gram-positive bacilli.
11. Differentiate *Arcanobacterium haemolyticum* from other non-spore-forming gram-positive bacilli and β -hemolytic streptococci.
12. Differentiate *Gardnerella vaginalis* from other non-spore-forming gram-positive bacilli on the basis of pathogenesis and laboratory identification.
13. Justify using a Gram stain of vaginal discharge instead of culture to diagnose bacterial vaginosis.
14. Describe the clinical infections associated with *Nocardia*, *Actinomadura*, and *Streptomyces*.
15. Differentiate infections caused by *Nocardia*, *Actinomadura*, *Streptomyces*, *Gordonia*, and *Rhodococcus* from infections caused by fungal agents.
16. Describe *Tropheryma whippelii* and Whipple disease.
17. Compare the appearance of bacterial spores when visualized with Gram stain and spore stain.
18. Describe the clinical infections associated with *Bacillus anthracis*.
19. Compare the relationship among the three exotoxin proteins of *B. anthracis*.
20. Describe the differential tests used to identify *B. anthracis*.
21. Discuss the clinical significance of *Bacillus* spp. other than *B. anthracis*.
22. Describe the clinical significance of *Bacillus cereus*.
23. Differentiate *B. anthracis* from other *Bacillus* spp.

A 76-year-old female patient who was receiving corticosteroid therapy for a malignant tumor complained to her physician of fever and headache of 7 days' duration. Her headache had become progressively worse, and her temperature was elevated. A complete blood count was performed and showed a slightly elevated white blood cell (WBC) count with normal distribution. A lumbar puncture was performed, and the following laboratory results were obtained from the cerebrospinal fluid (CSF):

- 250 WBC/mL
- Glucose 30 mg/dL (serum glucose was 105 mg/dL)
- Protein 180 mg/dL

No bacteria were observed on a Gram-stained smear of the CSF. The CSF was inoculated onto sheep blood agar (SBA) and chocolate agar. β -Hemolytic colonies grew on the SBA 2 days later. Similar colony growth was present on the chocolate agar. Gram stain morphology revealed a pleomorphic, gram-positive, non-spore-forming bacillus. The isolate had the following biochemical characteristics:

- Catalase positive
- Esculin hydrolysis positive
- Hippurate hydrolysis positive
- Motile at room temperature, but not at 35° C
- Christie, Atkins, Munch-Peterson (CAMP) test positive (block, not arrow shaped)

Issues to consider

After reading the patient's case history, consider:

- Key tests to be performed to differentiate non-spore-forming gram-positive bacilli
- Factors that increase an individual's risk for infection by non-spore-forming gram-positive bacilli
- The distribution in nature of non-spore-forming gram-positive bacilli and the species that constitute the normal bacterial biota of humans

This chapter discusses a large diverse group of bacteria commonly encountered in the clinical microbiology laboratory. Most species are found in the environment and are easily isolated from water and soil. Most of these organisms are not highly pathogenic but are being isolated from clinical infections with increasing frequency. Bacteria that belong to the aerobic, gram-positive bacilli group include the spore-forming genus *Bacillus*; non-spore-forming bacteria, including the genera *Corynebacterium*, *Arcanobacterium*, *Rhodococcus*, *Listeria*, *Erysipelothrix*, and *Gardnerella*; and branching, non-spore-forming aerobic actinomycetes, including *Nocardia*. Fig. 16.1 shows a schematic diagram for the presumptive identification of aerobic, gram-positive bacteria. Members of the genus *Lactobacillus* are non-spore-forming gram-positive rods, which are frequently isolated from urogenital specimens from women and are incubated aerobically. However,

these organisms are aerotolerant anaerobes and are discussed in Chapter 22.

A wide range of clinical conditions results from infection with these organisms. Although several of these organisms are frequently isolated in the clinical laboratory, they are typically considered contaminants or commensals (e.g., *Bacillus* and *Corynebacterium*). Several of these organisms are rarely encountered but cause significant disease (*Listeria*, *Erysipelothrix*, *Corynebacterium diphtheriae*, and *Bacillus anthracis*). For some species, the frequency of isolation is increasing, and new clinical syndromes are being established, especially in immunocompromised patients. As genetic and molecular biology tools progress, the diversity of many of these genera is being identified (e.g., *Nocardia*, *Corynebacterium*), and new clinical correlations are being made.

Non-spore-forming, nonbranching, catalase-positive bacilli

Corynebacterium

General characteristics

The genus *Corynebacterium* is a large diverse group of bacteria that includes animal and human pathogens as well as saprophytes and plant pathogens. There are more than 200 species in the genus. Most of the species are found as normal microbiota on the skin and mucous membranes of humans and animals, and some species are found worldwide in the environment. On the basis of 16S ribosomal ribonucleic acid (rRNA) sequencing, corynebacteria are closely related to mycobacteria and nocardiae. *Corynebacterium* can be divided into nonlipophilic and lipophilic species. Lipophilic corynebacteria are often considered fastidious and grow slowly on standard culture media; cultures often must be incubated for at least 48 hours before growth is detected. However, growth is enhanced if lipids are included in the culture medium.

On Gram stain, corynebacteria are slightly curved, gram-positive bacilli with nonparallel sides and slightly wider ends, producing the described "club shape" or coryneform. The term *diphtheroid*, meaning "diphtheria-like," is sometimes used in reference to this microscopic morphology for nonpathogenic species. The classification of corynebacteria continues to evolve. There is a low rate of accurate species-level identification for many clinical isolates when using traditional biochemical methods of identification, and it is not possible to identify a significant proportion of coryneform-like isolates to the species level without matrix-assisted laser desorption/ionization-time-of-flight (MALDI-TOF) mass spectrometry or 16S DNA gene sequencing.

The most significant pathogen of the group, *C. diphtheriae*, has been extensively studied and is well characterized. Disease caused by *C. diphtheriae* is referred to as **diphtheria**. Nondiphtheria *Corynebacterium* spp. are frequently isolated from clinical specimens, and they are often dismissed as commensal microbiota. However, similar to many organisms previously thought to be commensal nonpathogenic organisms, *Corynebacterium* spp. isolated from various body sites are opportunistic pathogens, especially in immunocompromised patients. Nondiphtheria *Corynebacterium* spp. that

Fig. 16.1 Schematic diagram for the identification of Gram-positive bacteria. *Lactobacillus* is an aerotolerant anaerobe discussed in Chapter 22. H_2S , Hydrogen sulfide.

produce disease in humans include, but are not limited to, *Corynebacterium amycolatum*, *Corynebacterium pseudodiphtheriticum*, *Corynebacterium pseudotuberculosis*, *Corynebacterium jeikeium*, *Corynebacterium striatum*, *Corynebacterium ulcerans*, and *Corynebacterium urealyticum*.

Corynebacterium diphtheriae

Virulence factors

Diphtheria toxin is the major virulence factor associated with *C. diphtheriae*. This exotoxin is produced by strains of *C. diphtheriae* infected with a lysogenic corynebacteriophage that carries the *tox* gene for diphtheria toxin. Nontoxic strains can be converted to *tox* positive by infection with the appropriate corynebacteriophage. Toxin-producing *C. diphtheriae* causes diphtheria; however, *C. belfantii*, *C. ulcerans*, and *C. pseudotuberculosis* are part of a larger complex that can carry and produce the toxin.

Diphtheria toxin is a protein of 62,000 daltons (Da). It is composed of two fragments: A and B. The toxin is exceedingly potent and is lethal for humans in amounts of 100 ng/kg body weight. The toxicity is caused by the ability of diphtheria toxin to block protein synthesis in eukaryotic cells. The toxin is secreted by the bacterial cell and is nontoxic until exposed to

trypsin. Trypsinization cleaves the toxin into the two fragments, which are held together by a disulfide bridge. Both fragments are necessary for cytotoxicity. Fragment A is responsible for the cytotoxicity, and fragment B binds to receptors on human cells and mediates the entry of fragment A into the cytoplasm. On reaching the cytoplasm, fragment A disrupts protein synthesis. Fragment A splits nicotinamide adenosine dinucleotide to form nicotinamide and adenosine diphosphoribose (ADPR). ADPR binds to and inactivates **elongation factor 2 (EF-2), an enzyme required for elongation of polypeptide chains on ribosomes**. Inactivation of EF-2 inhibits protein synthesis.

Production of the toxin in vitro depends on numerous environmental conditions, including an **alkaline pH (7.8 to 8.0)**, oxygen, and, **most importantly, the iron concentration in the environment**. The amount of iron needed for optimal toxin production is less than the amount needed for optimal growth. The toxin is released in significant amounts only when the available iron in the culture medium is exhausted.

Clinical infections

C. diphtheriae causes two different forms of disease in humans: **respiratory and cutaneous diphtheria**. Respiratory diphtheria is found worldwide but is uncommon in North America and western Europe because of widespread **vaccination**.

In the United States since universal vaccination began in the 1940s, cases occur most often in nonimmunized populations. Between 2004 and 2019, only five probable or confirmed diphtheria cases were reported. However, the number of diphtheria cases reported globally has been increasing gradually. The World Health Organization estimates that less than 16,000 cases were reported in 2018, which is more than double the yearly average for the prior decade. The U.S. Centers for Disease Control and Prevention (CDC) recommends that international travelers ensure that they are up to date on all vaccinations. Individuals who were vaccinated as children and have not been revaccinated as adults are susceptible to infection.

Humans are the only natural hosts for *C. diphtheriae*. Both toxigenic and nontoxigenic strains can cause infection; however, disease caused by nontoxigenic strains is typically less severe and less invasive. The bacteria are carried in the upper respiratory tract and spread by **droplet or hand-to-mouth contact**. The incubation period averages 2 to 5 days. The illness begins gradually and is characterized by low-grade fever, malaise, and a mild sore throat. The most common site of infection is the tonsils or the pharynx. The organisms rapidly multiply on the epithelial cells, and the toxigenic strains of *C. diphtheriae* produce toxin locally, causing tissue necrosis and exudate formation and triggering an inflammatory reaction. This combination of cell necrosis and exudate forms a tough gray-to-white pseudomembrane that attaches to the tissues. It may appear on the tonsils and then spread downward into the larynx and the trachea. There is the potential for suffocation if the membrane blocks the air passage or if it is dislodged, perhaps as the result of sampling for a throat culture.

The toxin is also absorbed and can produce various systemic effects involving the **kidneys, heart, and nervous system**, although most cells possess the receptor for the toxin and may be affected. Death often is a result of cardiac failure. Another effect of the toxin is a demyelinating peripheral neuritis, which can result in paralysis following the acute illness.

Other nonrespiratory sites may be infected, although much less often compared with the upper respiratory tract. In the cutaneous form of diphtheria, which is prevalent in the tropical regions of the world, the toxin also is absorbed systemically, but systemic complications are less common than those of upper respiratory tract infections. Cutaneous diphtheria caused by toxigenic strains consists of nonhealing ulcers with a dirty gray membrane. Although this form is unusual in the United States, there have been outbreaks caused by close person-to-person contact. When isolated in culture from cutaneous disease, *C. diphtheriae* is often recovered along with ***Streptococcus pyogenes* and *Staphylococcus aureus***. In addition, with the adoption of MALDI-TOF mass spectrometry in clinical microbiology laboratories, there has been an increased rate of reporting for *C. diphtheriae* from cutaneous samples.

An effective toxoid vaccine—formalin-treated diphtheria toxin—is available. It is part of the trivalent diphtheria, tetanus, and pertussis (acellular pertussis for pediatric formulations) vaccine. Children receive a series of five injections beginning at 2 months of age, with the fifth administered between 4 and 6 years of age. A combination diphtheria-tetanus vaccine is recommended every 10 years thereafter. The

vaccine induces antibody to diphtheria toxin, preventing disease but not infection by *C. diphtheriae*.

Laboratory diagnosis

Microscopy

C. diphtheriae is a highly **pleomorphic (many shapes) gram-positive bacillus that appears in palisades (cells lie in parallel rows) or as individual cells lying at sharp angles to each other in V and L formations**. Although they may be demonstrated by other *Corynebacterium* spp., club-shaped swellings and beaded forms are common (Fig. 16.2). The organisms often stain irregularly, especially when stained with methylene blue, giving them a beaded appearance. The metachromatic areas of the cell, which stain more intensely than other parts, are called **Babès-Ernst granules**. They represent accumulation of polymerized polyphosphates. The presence of Babès-Ernst granules indicates the accumulation of nutrient reserves and differs with the type of medium and the metabolic state of the individual cells.

Culture characteristics

C. diphtheriae is a facultative anaerobe. It grows best under aerobic conditions and has an optimal growth temperature of 37° C, although multiplication occurs within the range of 15° to 40° C. Although *C. diphtheriae* grows on nutrient agar, better growth is usually obtained on a medium containing blood or serum, such as **Loeffler serum or Pai agars**. Characteristic microscopic morphology is demonstrated well when organisms are grown on **Loeffler medium**. On SBA (Fig. 16.3), the organism can have a very small zone of β -hemolysis.

Cystine-tellurite blood agar (CTBA), a modification of Tinsdale medium, contains sheep red blood cells, bovine serum, cystine, and potassium tellurite. CTBA is both a selective medium and a differential medium. The potassium tellurite inhibits many noncoryneform bacteria. When grown on CTBA, corynebacteria form black or brownish colonies from the reduction of tellurite. However, this appearance is not unique for *C. diphtheriae*, so care must be taken not to presumptively identify other genera that produce black colonies (e.g., *Staphylococcus* and *Streptococcus*) as *Corynebacterium*.

Identification

The biochemical identification of medically important corynebacteria is outlined in Table 16.1. All medically important corynebacteria are catalase positive and nonmotile. CTBA is useful for differentiating corynebacteria because only *C. diphtheriae*, *C. belfantii*, *C. ulcerans*, and *C. pseudotuberculosis* form a brown halo as a result of cystinase activity. *C. diphtheriae* and *C. belfantii* are distinguished from the other two species by its lack of urease production, and *C. belfantii* can be differentiated from *C. diphtheriae* based on the ability to reduce nitrate. *C. diphtheriae* ferments glucose and maltose, producing acid, but not gas, and reduces nitrate to nitrite. The three biotypes of *C. diphtheriae*, *gravis*, *intermedius*, and *mitis*, can be separated using biochemical assays. A schematic diagram for presumptive identification of *C. diphtheriae* is shown in Fig. 16.4. MALDI-TOF mass spectrometry has been shown to accurately identify the potentially toxigenic strains of *Corynebacterium* spp., but it may not be able to differentiate *C. belfantii* from *C. diphtheriae*.

Test for toxigenicity

The identification of an isolate as *C. diphtheriae* does not mean that the patient is infected with a toxigenic strain. Determination of the presence of toxin is important for patient management and infection prevention. The growth medium and conditions markedly affect toxin production. The iron content of the medium must be growth rate limiting for full toxin production. The addition of iron to iron-starved cultures quickly inhibits toxin production. In vivo toxin testing is rarely done because the in vitro methods are reliable, less expensive, and free from animal use.

The in vitro diphtheria toxin detection procedure is an immunodiffusion test first described by Elek. In the Elek test, organisms (controls and unknowns) are streaked on medium of low iron content. Each organism is streaked in a single straight line parallel to each other and 10mm apart. A filter paper strip impregnated with diphtheria antitoxin is laid along the center of the plate on a line at right angles to the inoculum lines of control and unknown organisms (Fig. 16.5). The plate is incubated at 35° C and examined after 18, 24, and 48 hours. Lines of precipitation are best seen by transmitted light against a dark background. The white precipitin lines start about 4 to

5mm from the filter paper strip and are at an angle of about 45 degrees to the line of growth. If an isolate is positive for toxin production and it is placed next to the positive control, the toxin line of the positive control should join the toxin line of the positive unknown to form an arch of identity.

The Elek test requires that reagents and antisera be carefully controlled and titrated. Because of the difficulty of the test, it is performed only in certain reference laboratories. Rapid enzyme-linked immunosorbent assays and immuno-chromatographic strip assays are also available for the detection of diphtheria toxin. In addition, procedures for detecting the *C. diphtheriae* *tox* gene by polymerase chain reaction (PCR) have been developed by individual laboratories. The PCR assays can also be applied directly to clinical specimens.

Treatment

Diphtheria is treated by prompt administration of antitoxin. Commercial diphtheria antitoxin is produced from horse serum. Approximately 10% of patients who receive the antitoxin develop an allergic reaction to the horse serum. Consequently, hypersensitivity to horse serum precludes its administration. Antimicrobial agents have no effect on the toxin that is already circulating, but they do eliminate the focus of infection and prevent the spread of the organism. The drug of choice is penicillin; erythromycin is used for penicillin-sensitive individuals. Most patients do not develop immunity after infection; therefore vaccination should be administered after recovery.

Other corynebacteria

Corynebacterium amycolatum

C. amycolatum is one of the *Corynebacterium* species most frequently recovered from human specimens. It is part of the normal skin microbiota and has often been misidentified by clinical laboratories as *C. striatum*, *C. xerosis*, and *C. minutissimum*. It is often associated with prosthetic joint- or hardware-associated infections, and it has also been reported to cause mastitis, peritonitis, and bloodstream infection and endocarditis, typically in immunocompromised patients or in patients in a health care setting.

Colonies of *C. amycolatum* are flat and dry, have a matte or waxy appearance, and are nonlipophilic. Most strains have been reported to be resistant to a wide range of antimicrobials, including β -lactams, fluoroquinolones, macrolides, clindamycin, and aminoglycosides.

Corynebacterium jeikeium

C. jeikeium, named after Johnson and Kaye, who first linked this organism with human infections, appears to be part of the normal skin microbiota. Infections are typically limited to patients who are immunocompromised, have undergone invasive procedures, have central line catheters, or have prosthetic or other hardware devices. It is the most common cause of *Corynebacterium*-associated prosthetic valve endocarditis in adults. Infection is more likely to require valve replacement, and mortality rates as high as 33% have been reported in these patients. *C. jeikeium* also causes septicemia, meningitis, prosthetic joint infections, and skin complications, such as rash and subcutaneous nodules.

Fig. 16.5 Elek test for toxin-producing strains of *Corynebacterium diphtheriae*. 1, Positive control; 2, unknown (toxigenic); 3, negative control; 4, unknown (nontoxigenic).

The organism is lipophilic and a strict aerobe that is non-hemolytic, does not produce urease, and is nitrate reduction negative. *C. jeikeium* has been reported to be resistant to a wide range of antimicrobials, including penicillins, cephalosporins, macrolides, and aminoglycosides. Multidrug resistance cannot be used as the only identifying characteristic because several *Corynebacterium* species, such as *C. amycolatum*, exhibit similar multidrug-resistance patterns. The drug of choice for treating *C. jeikeium* infections is vancomycin.

Corynebacterium pseudodiphtheriticum

C. pseudodiphtheriticum, which is part of the normal biota of the human nasopharynx, is an infrequent cause of infection. It is most frequently associated with respiratory tract infections in immunocompromised individuals or patients with other underlying diseases, such as chronic obstructive pulmonary disease or diabetes mellitus. It was identified in association with ventilator-associated pneumonia in cases of coronavirus disease 2019 (COVID-19). In some cases, respiratory tract infection can mimic respiratory diphtheria. In addition, *C. pseudodiphtheriticum* has been reported to cause endocarditis, urinary tract infections (UTIs), and cutaneous wound infections in immunocompromised patients. In contrast with other corynebacteria, *C. pseudodiphtheriticum* does not show the characteristic pleomorphic morphology. The cells stain evenly and often appear in palisades. The species grows well on standard laboratory media, reduces nitrate, and produces urease.

Corynebacterium pseudotuberculosis

C. pseudotuberculosis is primarily a veterinary pathogen. Human infections typically have been associated with contact with sheep and are rare. *C. pseudotuberculosis* causes a granulomatous lymphadenitis in humans. The organism produces a dermonecrotic toxin that causes death of various cell types, and it can produce diphtheria toxin. Similarly to *C. diphtheriae*, *C. pseudotuberculosis* also produces a brown halo on CTBA. *C. pseudotuberculosis* produces urease and on SBA forms small, yellowish-white colonies.

Corynebacterium striatum

C. striatum is part of the human skin and the nasopharynx microbiota and is frequently isolated in clinical microbiology laboratories. This organism is often considered a commensal organism or skin "contaminant." However, hospital-acquired infections have been reported, and clinical case reports support the characterization of this organism as an emerging pathogen in immunocompromised as well as immunocompetent patients. *C. striatum* has been most commonly associated with device-related infection and has been reported in cases of endocarditis, septic arthritis, meningitis, and pneumonia. The organism is nonlipophilic and pleomorphic, and it often produces small, shiny, convex colonies in about 24 hours, which grow to appear striated with continued incubation. *C. striatum* has shown resistance to penicillins and other β -lactams, macrolides, and fluoroquinolones but is typically susceptible to vancomycin. Resistance to daptomycin, including high-level resistance (MIC = >256 μ g/mL), has been reported recently.

Corynebacterium ulcerans

Although an infrequent cause of infection, *C. ulcerans* has been isolated from humans with diphtheria-like illness, and a significant number of isolates produce diphtheria toxin. It has been isolated from skin ulcers and exudative pharyngitis. This organism is also a veterinary pathogen, causing mastitis in cattle and other domestic and wild animals. Human infections are usually acquired through contact with animals or by ingestion of unpasteurized dairy products. It produces a brown halo around colonies on CTBA. The organisms grow well on SBA and produce a narrow zone of β -hemolysis.

C. ulcerans is urease positive and does not reduce nitrate, differentiating it from *C. diphtheriae*.

Corynebacterium urealyticum

C. urealyticum is most commonly associated with UTIs. This organism is lipophilic and is a strict aerobe. Presumptive identification of *C. urealyticum* can be made for urine isolates with pinpoint, nonhemolytic, white colonies that have characteristic coryneform microscopic morphology. *C. urealyticum* is nitrate negative, catalase positive, and urease positive within minutes after inoculation on a Christensen urea slant. Resistance has been reported for a broad range of antimicrobials, including β -lactams, aminoglycosides, and trimethoprim-sulfamethoxazole. Some isolates have also demonstrated resistance to fluoroquinolones, macrolides, and tetracycline. The drug of choice for *C. urealyticum* infections is vancomycin.

Identification of coryneform bacteria

Coryneform bacteria are often identified to the species level (1) if they are isolated from normally sterile sites, particularly cerebrospinal fluid and from two or more blood cultures; (2) if they are the predominant organism from properly collected (not contaminated with commensal microbiota) clinical material; (3) if they are the predominant organism from urine samples when the total colony count is greater than 10^5 /mL or if they are the sole isolate with a colony count greater than 10^4 /mL; and (4) for *Corynebacterium* spp. if they are the only isolate in patients with symptomatic pneumonia. Because the clinical significance of *Corynebacterium* spp. can differ, details regarding the specimen type, method of collection, and other patient-related factors should be taken into consideration for identification of these organisms.

In addition to conventional biochemical testing, commercial identification systems presently available include the RapID CB Plus system (Thermo Scientific, Waltham, MA), API Rapid Coryne system (bioMérieux, Durham, NC), Microscan ID panel (Beckman Coulter, Sacramento, CA), BBL Crystal GP system (BD Diagnostics, Sparks, MD), and VITEK 2 ANC card (bioMérieux). Although these systems have short incubation times ranging from a few hours to 48 hours, users should keep the limitations of these systems in mind. The test systems perform best with species that grow rapidly in ambient air and do not require nutritional supplements. Accurately identifying less frequently isolated species is difficult with many of these systems.

Many clinical microbiology laboratories, especially in academic medical centers and reference laboratories, use MALDI-TOF mass spectrometry for the identification of bacteria isolated from clinical cultures (see Chapter 11). This technology is rapid and has the ability to accurately identify many *Corynebacterium* isolates to the species level compared with biochemical systems. Studies have reported 89% to 94% accuracy in identification to the species level. However, accuracy of identification is organism and system dependent; therefore some species with similar deoxyribonucleic acid (DNA) sequences are not clearly differentiated by MALDI-TOF mass spectrometry. It is recommended that clinically significant, unidentifiable coryneform bacteria be sent to a reference laboratory for complete characterization. Many reference laboratories now use MALDI-TOF mass spectrometry or 16S DNA gene sequencing to identify species of coryneform bacteria and other coryneform bacteria.

Rothia

Rothia spp., which are actually gram-positive cocci that can appear rodlike, belong to the family Micrococcaceae. Of the greater than 10 species in the genus, at least 3 are regarded as clinically significant. *Rothia mucilaginosa* has been linked to bacteremia, endocarditis, pneumonia, and other infections. *R. mucilaginosa* is usually coccoid on Gram stain. Colonies of *R. mucilaginosa* can be whitish or gray, mucoid, and are often “sticky” (adherent to the agar). *Rothia dentocariosa*, which is typically, but not always, rod shaped, is a member of the normal human oropharyngeal microbiota and may be found in saliva and supragingival plaque. It has been isolated from patients with endocarditis. Microscopically, this organism resembles coryneform bacilli, forming not only short, gram-positive bacilli but also branching filaments that resemble filaments of facultative actinomycetes. However, when placed in broth, the species produces coccoid cells, a characteristic differentiating it from actinomycetes. Colonies of *R. dentocariosa* are usually white and may be either smooth or rough. Over time, the colonies may look wrinkled. *Rothia aeria* was first described in 2004 after the organism was isolated from the air in the Russian space station Mir. Since then, *R. aeria* has been recovered from abscesses from various sites, bacteremia, endocarditis, joint infections, and respiratory infections. Microscopically *R. aeria* may also form rods or filaments. Colonies of *R. aeria* are initially white and smooth but become dry and wrinkled. The colonies may adhere to the agar. *R. mucilaginosa*, *R. dentocariosa*, and *R. aeria* are members of the human oral biota. Other members of the genus are environmental. *Rothia* is nitrate positive, nonmotile, esculin hydrolysis positive, and urease negative. The catalase reaction is variable for most *Rothia* strains.

Related genera

Numerous related genera are occasional isolates in clinical laboratories; many are thought to belong to the normal biota and are generally considered commensal organisms or are environmental. Examples include *Brevibacterium*, *Cellulomonas*, *Microbacterium*, *Janibacter*, *Oerskovia*, *Paraoerskovia*, and *Dermabacter*.

Listeria monocytogenes

General characteristics

The genus *Listeria* contains over 20 species. Only *Listeria monocytogenes* is considered an important human pathogen, whereas *Listeria ivanovii* is primarily an animal pathogen but has been linked to rare systemic infections in humans with underlying conditions. *L. monocytogenes* is widespread in the environment and has been recovered from soil, water, vegetation, and animal products, such as raw milk, cheese, poultry, and processed meats. It also has been isolated from crustaceans, flies, and ticks. *L. monocytogenes* has long been known to cause illness in many species of wild and domestic animals, including sheep, cattle, swine, horses, dogs, cats, rodents, birds, and fishes, and it can be isolated from both human and animal asymptomatic carriers.

Listeriosis is recognized as an uncommon but serious infection primarily of neonates, pregnant women, older adults, and immunocompromised hosts. Infection may also occur in

healthy individuals. Each year, approximately 1600 cases of listeriosis are reported in the United States, resulting in 260 deaths. Large, multistate outbreaks of illness caused by *L. monocytogenes* have occurred several times, usually associated with foods, such as various types of cheese or deli meats. One of the larger multistate outbreaks, which was linked to cantaloupes from a Colorado farm, occurred in the United States in 2011 and resulted in 147 cases and 33 deaths.

Virulence factors

L. monocytogenes produces many products that have been proposed as virulence factors. These include internalin, listeriolysin O, phospholipase C, actin polymerizing protein, superoxide dismutase, and a surface protein (p60). Once ingested, *L. monocytogenes* survives initial host defenses such as proteolytic enzymes and low pH. The organism then adheres to and invades host cells with proteins from the internalin family. When invading a host cell, *L. monocytogenes* becomes trapped in a vacuole. The organism then produces listeriolysin O, a hemolysin, which forms a pore in the vacuole and facilitates escape into the cytoplasm. The correlation between listeriolysin O production and virulence is strong; strains without listeriolysin O are avirulent. Phospholipase C is also involved in *L. monocytogenes* escape from the vacuole. When the organism reaches the cytoplasm, it infects other cells with the aid of actin polymerizing protein. This protein polymerizes actin molecules into actin filaments. *L. monocytogenes* uses these filaments to move to adjacent cells. The protein p60 induces phagocytosis through increased adhesion and penetration into mammalian cells.

Clinical infections

The infectious dose of listeriosis is not well understood. The majority of infections are caused by ingestion of contaminated food products such as meat, poultry, cheese, and raw milk with subsequent spread through the intestine. *L. monocytogenes* appears to have a tropism for the central nervous system (CNS), and a high mortality rate (20% to 50%) is seen in patients with CNS infections. The clinical manifestations of listeriosis differ among patient groups. Infections of newborns and immunocompromised adults are the most common, but disease in healthy individuals, particularly in pregnant women, also occurs.

Disease in pregnant women

During pregnancy, listeriosis is most commonly seen during the third trimester. It has been postulated that *L. monocytogenes* is responsible for spontaneous abortion and stillborn neonates. A pregnant woman with listeriosis may experience a flulike illness with fever, headache, and myalgia. At this point, the organism is in the bloodstream and has seeded the uterus and the fetus. It may progress and result in premature labor or septic abortion within 3 to 7 days. It appears that the infection often is self-limiting because the source of the infection is eliminated when birth occurs.

Disease in the newborn

Infection of neonates with *L. monocytogenes* is extremely serious; fatality rates approach 50% if the fetus is born alive. Similar to *Streptococcus agalactiae* neonatal disease, there are two forms of neonatal listeriosis: early onset and late onset. Early-onset listeriosis results from an intrauterine infection that can cause illness at or shortly after birth. The result is most often sepsis. Early-onset disease may be associated with aspiration of infected amniotic

fluid. Late-onset disease occurs several days to weeks after birth. Affected infants generally are full-term infants and healthy at birth. The disease is most likely to manifest as meningitis. The fatality rate is lower than in early-onset infection, although it also is a very serious, potentially fatal infection.

Disease in the immunosuppressed host

Invasive listeriosis most commonly occurs in persons who are immunosuppressed or in older adults and particularly in patients receiving chemotherapy. Young children are also at risk for infection. In older adults and immunocompromised persons, the fatality rate is high. The most common manifestations are CNS infection and endocarditis. Diagnosis is made by culturing *L. monocytogenes* from blood or CSF.

Infection of apparently healthy individuals may occur through the intestinal tract when they eat food contaminated with *L. monocytogenes*. Outbreaks have occurred as a result of eating contaminated cheese, coleslaw, and chicken. Contaminated ice cream, hot dogs, and luncheon meats have served as vehicles for this foodborne disease. The penicillins, aminoglycosides, and macrolides have been effectively used to treat listeriosis. For invasive disease, ampicillin or penicillin in combination with gentamicin is the preferred treatment. Cephalosporins are inactive against *L. monocytogenes*. Resistance is uncommon, although some strains are resistant to one or more agents.

Case check 16.1

The Case in Point describing invasive disease in an older, immunosuppressed patient is typical for *L. monocytogenes* infection. Also, the phenotypic characteristics of the isolate are most consistent with *L. monocytogenes*. *L. monocytogenes* is β -hemolytic on SBA, catalase positive, motile at room temperature but not at 35°C, esculin hydrolysis positive, hippurate hydrolysis positive, and block shape positive with the CAMP test. Typically, most people who contract *L. monocytogenes* infection consume contaminated food, such as dairy products or meat.

Laboratory diagnosis

Microscopy

In direct smears (Fig. 16.6), *L. monocytogenes* appears as a gram-positive coccobacillus. With subculturing, cells become coccoidal (Fig. 16.7). Older cultures often appear gram variable. Cells may be found singly, in short chains, or in palisades. Depending on the culture conditions, *L. monocytogenes* can resemble *Streptococcus* when found in the coccoid form and *Corynebacterium* when the bacillus forms prevail. Organisms are not usually seen on the CSF smear.

Cultural characteristics

L. monocytogenes grows well on SBA and chocolate agar as well as on nutrient agars and in broths, such as brain-heart infusion medium and thioglycolate broth. The organism prefers a slightly increased carbon dioxide (CO₂) tension for isolation. The colonies are small, round, smooth, and translucent. They are surrounded by a narrow zone of β -hemolysis, which may be visualized only if the colony is removed. The colonies and hemolysis resemble those seen with *S. agalactiae* (Fig. 16.8A).

The optimal growth temperature for *L. monocytogenes* is 30°C to 35°C, but growth occurs over a wide range (0.5°C to 45°C).

Because *L. monocytogenes* grows at 4° C, a technique called **cold enrichment** may be used to isolate the organism from polymicrobial clinical specimens. The specimen is placed into broth and incubated at 4° C for several weeks. Subcultures are made at weekly intervals and examined for *L. monocytogenes*. Most bacteria grow more slowly than *L. monocytogenes* at this

Fig. 16.6 Gram stain of *Listeria monocytogenes* in the blood (×1000). (Courtesy Cathy Bissonette.)

temperature. The length of time required for isolation using this method lessens its importance in the clinical setting because treatment must begin early in the infectious process.

Identification

The diagnosis of listeriosis depends on isolating *L. monocytogenes* from **blood, CSF, or swabs taken from lesions**. Table 16.2 lists the characteristics of *L. monocytogenes* and bacteria with similar colony morphologies. *L. monocytogenes* is **hippurate hydrolysis positive like *S. agalactiae*, but unlike *S. agalactiae*, it is catalase positive, bile esculin hydrolysis positive, and motile at room temperature**. In wet mount preparations, *L. monocytogenes* exhibits **tumbling motility (end-over-end motility) when viewed microscopically**. In motility medium, the characteristic **“umbrella” pattern** is seen when the organism is incubated at room temperature (22° to 25° C) but not at 35° C (Fig. 16.9).

L. monocytogenes produces a positive CAMP reaction; a more pronounced CAMP reaction is seen with *L. monocytogenes* when *Rhodococcus equi* is used in place of *Staphylococcus aureus*. *L. monocytogenes* produces a **“block”-type hemolysis with the CAMP test**. This type of hemolysis is in contrast with the **“arrowhead” type produced by *S. agalactiae* (group B *Streptococcus*)** (see Fig. 16.8B). The positive CAMP reaction distinguishes *L. monocytogenes* from other *Listeria* spp., which are CAMP test negative. A presumptive identification can be made on the basis of the results of the Gram stain, tumbling motility, positive catalase, and esculin hydrolysis. Confirmatory findings include acid production from glucose and positive Voges-Proskauer and methyl red reactions. *L. monocytogenes* and other *Listeria* species are identified well by MALDI-TOF mass spectrometry.

Non-spore-forming, nonbranching, catalase-negative bacilli

Erysipelothrix rhusiopathiae

General characteristics

There are six species in the genus *Erysipelothrix*: *Erysipelothrix rhusiopathiae*, *E. tonsillarum*, *E. inopinata*, *E. larvae*, *E. muris*, and *E. piscisicarius*. *E. rhusiopathiae* is the only species in the genus known to cause disease in humans. **It is a gram-positive, catalase-negative, non-spore-forming, pleomorphic rod that has a tendency to form long filaments**. It is found worldwide and

is a commensal or a pathogen in a wide variety of vertebrates and invertebrates, including domestic swine, birds, and fishes. Human cases typically result from occupational exposure. Individuals whose work involves handling fish and animal products are most at risk. The usual route of infection is through cuts or scratches on skin. The organism is resistant to salting, pickling, and smoking, and it survives well in environmental sources such as water, soil, and plant material.

Clinical infections

E. rhusiopathiae produces three types of disease in humans: erysipelas, which is a localized skin disease; septicemia, which is often associated with endocarditis; and a generalized, diffuse cutaneous infection. The incidence of *E. rhusiopathiae* infections is low. Systemic infection is uncommon and rarely develops from erysipelas. Endocarditis has been seen in patients who have had valve replacements as well as in individuals with apparently normal heart valves. Risk factors for endocarditis include a history of heart disease and a history of alcohol abuse. Endocarditis caused by *E. rhusiopathiae* has a 38% mortality rate, and approximately one third of patients who develop endocarditis must undergo valve replacement.

Erysipelas, the most common infection caused by *E. rhusiopathiae* in humans, is a localized skin infection that resembles streptococcal erysipelas. The lesions usually are seen on the hands or fingers because the organisms usually are inoculated through work activities. The incubation period is 2 to 7 days.

The infected area is painful and swollen and gives rise to a characteristic lesion—a sharply defined, slightly elevated, purplish red zone that spreads peripherally as discoloration of the central area fades. Low-grade fever, arthralgia, lymphangitis, and lymphadenopathy may occur. Erysipelas is a self-limiting infection that normally heals within 3 to 4 weeks but may continue for months. Relapses are known to occur.

The generalized, diffuse cutaneous disease caused by *E. rhusiopathiae* is rare and manifests itself as an exacerbation of the erysipelas lesion. This cutaneous disease tends to last longer than erysipelas and relapses as well. Penicillin or amoxicillin are the drugs of choice for treating both cutaneous and systemic infections. *E. rhusiopathiae* is routinely resistant to vancomycin.

Laboratory diagnosis

Microscopy

E. rhusiopathiae is a thin, rod-shaped, gram-positive organism that can form long filaments (Fig. 16.10). It is arranged singly, in short chains, or in a V shape. The last arrangement is similar to that seen with corynebacteria. *E. rhusiopathiae* decolorizes easily, so it may appear gram variable.

Culture characteristics

Typical specimens received for the isolation of *E. rhusiopathiae* include tissue biopsy or aspirates from skin lesions. These should be inoculated into a nutrient broth with 1% glucose and incubated in 5% CO₂ at 35° C. The organism also grows on standard culture media, including SBA and chocolate agar. Subcultures from both should be inoculated daily onto SBA plates. On SBA, the colonies are usually nonhemolytic and pinpoint after 24 hours of incubation. The colonies of *E. rhusiopathiae* and *L. monocytogenes* are compared in Fig. 16.11. After 48 hours of incubation, two distinct colony types are seen: A smaller, smooth form is transparent, glistening, and convex with entire edges; the larger, rough colonies are flatter with a matte surface, curled structure, and irregular edges. The colonies often appear α -hemolytic after a few days of growth. In addition, *E. rhusiopathiae* grows in blood culture media from systemic infections.

Identification

Table 16.3 lists the characteristics of *Erysipelothrix* and similar gram-positive bacilli. A catalase-negative, nonmotile, pleomorphic, aerobic or facultatively anaerobic, gram-positive rod that is hydrogen sulfide positive is suggestive of *E. rhusiopathiae*. In addition, the organism is Voges-Proskauer test negative. Growth of *E. rhusiopathiae* in a gelatin stab culture yields a highly characteristic “test tube brush-like” pattern at 22° C. *E. rhusiopathiae* is identified well by MALDI-TOF mass spectrometry.

Arcanobacterium and Trueperella

In 2011, some members of the genus *Arcanobacterium* were moved to the genus *Trueperella*. The primary human pathogen of the genus *Arcanobacterium* is *A. haemolyticum*. *Trueperella pyogenes* and *Trueperella bernardiae* can also cause infections in

humans. *T. pyogenes* is an animal pathogen that is best known for causing infections in cattle. In humans, *T. pyogenes* is a rare cause of infections, such as sepsis and wound infections, and infections typically occur in individuals who have had contact with animals. *T. bernardiae*, also a rare cause of infections in humans, has been associated with bacteremia, wound infections, UTIs, and septic arthritis.

A. haemolyticum has been recovered from patients 10 to 20 years of age with pharyngitis and must be distinguished from *C. diphtheriae* and *C. ulcerans* as well as group A streptococci. Pharyngitis caused by *A. haemolyticum* can be mild or severe and is often clinically indistinguishable from pharyngitis caused by β -hemolytic streptococci. Most patients develop cervical lymphadenopathy, and approximately 50% of patients develop a pruritic, scarlatiniform rash and desquamation of the skin of the hands and feet. In addition, *A. haemolyticum* has been associated with soft tissue infections, sepsis, endocarditis, and other infections.

A. haemolyticum and clinically significant *Trueperella* spp. are catalase negative. *A. haemolyticum* produces small colonies on SBA that demonstrate a narrow zone of β -hemolysis after 24 to 48 hours of incubation similar in appearance to β -hemolytic streptococci (Fig. 16.12). Frequently, a black opaque dot is observed on the agar when the colony is scraped away. Pitting of the agar beneath the colony has also been reported. Gram staining of the isolated colony quickly rules out group A streptococci. Many of the rods are pleomorphic, and some cells may demonstrate rudimentary branching (Fig. 16.13). *A. haemolyticum* is both lipase and lecithinase positive. It exhibits a reverse CAMP reaction (CAMP inhibition reaction) because the hemolysis produced by a β -lysin-producing *S. aureus* is inhibited by a phospholipase D excreted by *A. haemolyticum*. They are CAMP test positive if *S. agalactiae* is used in place of *S. aureus*. All of these bacteria are identified well by MALDI-TOF mass spectrometry. Azithromycin is the drug of choice for treatment.

Gardnerella vaginalis

General characteristics

The genus *Gardnerella* includes four species. *G. vaginalis*, first described in 1953, is the primary species in the genus associated with human infections. It is found as normal biota in the human urogenital tract. *G. vaginalis* is a short, pleomorphic gram-positive rod or coccobacillus that often stains gram variable or gram negative. *G. vaginalis* has a gram-positive type of cell wall; however, the peptidoglycan layer is

Table 16.3 Characteristics of *Listeria*, *Corynebacterium*, *Erysipelothrix*, and similar gram-positive bacilli

thinner than that found in other gram-positive bacteria such as *Corynebacterium* and *Lactobacillus*.

Clinical infections

G. vaginalis is primarily known for its association with **bacterial vaginosis** (BV) in humans, the most common vaginal condition in women 15 to 44 years of age. For years, *G. vaginalis* was thought to be the only cause of BV. However, the organism can be isolated from 40% of women without BV. More than likely, BV is a polymicrobial disease in which *G. vaginalis* and other bacteria, such as *Prevotella* spp., *Peptostreptococcus* spp., *Bacteroides* spp., *Porphyromonas* spp., *Mobiluncus* spp., *Megasphaera* spp., *Sneathia* spp., *Fusobacterium* spp., *Atopobium vaginae*, *Mycoplasma hominis*, *Ureaplasma urealyticum*, and members of the class *Clostridia*, are involved. BV is characterized by a malodorous discharge and vaginal pH greater than 4.5. BV generally results from a reduction in the *Lactobacillus* population in the vagina, followed by an increase in vaginal pH; this results in overgrowth of BV-associated organisms that make up the normal vaginal biota. *G. vaginalis* can also play a role in UTIs in men and women. The organism has rarely been isolated from other clinical sources, such as blood cultures or wounds. The drug of choice to treat BV is metronidazole, although clindamycin is also often used.

Laboratory diagnosis

Microscopy

Gram staining of vaginal secretions is generally regarded as the reference method for diagnosing BV. The observation of “clue cells,” large squamous epithelial cells with gram-positive and gram-variable bacilli and coccobacilli clustered on the edges, aids the diagnosis of BV, particularly if *Lactobacillus* rods are absent in the wet mount. *G. vaginalis* often appears as a pleomorphic, gram-variable coccobacillus or short rod. The cells often stain gram negative and are 1.5 to 2.5 μm in length. The Nugent scoring system for Gram-stained vaginal smears is a more accurate means of diagnosing BV than cultures (Table 16.4). Stained smears are examined and scored for the presence of *Lactobacillus*, *Gardnerella*, and *Mobiluncus* morphotypes. **In addition, clue cells can be visualized in wet mounts of vaginal fluid when BV is suspected.**

Additional identification methods

Amsel's clinical criteria can also be used to diagnosis BV if three of four criteria are found: (1) homogeneous, thin, white discharge that smoothly coats the vaginal walls, (2) clue cells, (3) pH of vaginal fluid greater than 4.5, and (4) fishy odor of vaginal discharge before or after addition of 10% potassium hydroxide—the whiff test. In addition, the Affirm VP III test (Becton Dickinson, Sparks, MD), a DNA hybridization probe test for *G. vaginalis*, and the OSOM BV Blue test (Sekisui Diagnostics, Framingham, MA), which detects vaginal fluid sialidase activity, have acceptable performance compared with Gram staining of vaginal material.

Culture characteristics

Because *G. vaginalis* can be found as normal vaginal biota and its role in BV is questionable, cultures for *G. vaginalis* are infrequently performed. Vaginal discharge collected from suspected BV cases is the most common specimen used for the isolation of *G. vaginalis*. Because it is part of the urogenital microbiota, the organism can also be isolated from urine. It often takes longer than 24 hours to develop visible colonies, and *G. vaginalis* grows best in 5% to 7% CO₂ at a temperature of 35° to 37° C. *G. vaginalis* grows on SBA as pinpoint, nonhemolytic colonies. It also grows on chocolate agar. Additional media for the recovery of *G. vaginalis* include human blood bilayer Tween (HBT) agar or *Gardnerella* selective V (*vaginalis*) agar that also contains human blood. When cultured on human blood, colonies are β-hemolytic, small, gray, and opaque. *G. vaginalis* also produces β-hemolytic colonies on media made with rabbit blood but not sheep blood.

Identification

See Table 16.3 for a list of the key biochemical characteristics of *G. vaginalis* and other gram-positive bacilli. β-Hemolytic colonies on HBT agar should be suspected as *G. vaginalis*. MALDI-TOF mass spectrometry will identify this organism well. Some laboratories use 16S rRNA gene sequencing for definitive identification of *G. vaginalis*.

Table 16.4 Nugent scoring system for Gram-stained vaginal smears

Lactobacillus morphotypes (boxy, gram-positive bacilli)		Gardnerella and Bacteroides morphotypes (pleomorphic, gram-variable and gram-negative, short bacilli)		Mobiluncus morphotypes (curved, gram-variable bacilli)	
Quantity	Points	Quantity	Points	Quantity	Points
4+	0	0	0	0	0
3+	1	1+	1		
2+	2	2+	2	1+ to 2+	1
1+	3	3+	3		
0	4	4+	4	3+ to 4+	2

Interpretation: total score 0 to 3, normal vaginal microbiota; 4 to 6, indeterminate for bacterial vaginosis; 7 to 10, bacterial vaginosis.

Modified from Nugent, R. P., et al. (1991). Reliability of diagnosing bacterial vaginosis is improved by a standardized method of Gram stain interpretation. *J Clin Microbiol*, 29, 297.

Non-spore-forming, branching, aerobic actinomycetes

Nocardia

General characteristics

Nocardia spp. are aerobic, branched, beaded, gram-positive bacilli. The beads are not usually spaced at consistent intervals (Fig. 16.14A). In many instances, finely beaded, branching rods are a primary clue that a clinical sample contains *Nocardia* spp. In addition, *Nocardia* spp. are partially acid fast, meaning they retain the primary stain but only when a weak acid is used as the decolorizer during the acid-fast staining process (see Fig. 16.14B). This characteristic is also referred to as modified acid-fast positive. The acid-fast stain is used to visualize the mycobacteria and is discussed in Chapter 26.

The colony and microscopic morphology as well as the types of infections caused sometimes resemble those of fungi, but these organisms are true bacteria. *Nocardia* spp. can be recovered on standard nonselective media; however, growth may take 1 week or longer. Most *Nocardia* spp. are found worldwide in soil and on plant material, and several have been implicated in human infections. Generally, infections caused by *Nocardia* occur in immunocompromised patients.

Fig. 16.14 A, Gram stained smear of *Nocardia* demonstrating irregular staining (×1000). B, Acid-fast staining of *Nocardia* showing partially acid-fast appearance (×1000). (Courtesy Steve Mahlen and Amanda Harrington.)

However, reports of infection in patients with no apparent illness or immunosuppressive therapy are increasing.

The taxonomy of the genus is evolving and has expanded the number of species recognized as human pathogens. There are about 100 named *Nocardia* spp., and more than one half have reportedly been isolated from humans. The most commonly encountered species are *Nocardia brasiliensis*, *Nocardia cyriacigeorgica*, *Nocardia farcinica*, *Nocardia abscessus* complex, and *Nocardia nova*. Less commonly encountered species include *Nocardia otitidiscaviarum*, *Nocardia pseudobrasiliensis*, *Nocardia paucivorans*, *Nocardia africana*, and *Nocardia transvalensis*. At one time, *Nocardia asteroides* was considered the most prominent *Nocardia* human pathogen. With the more frequent use of molecular methods for identification, it has since been found that *N. asteroides* is a rare human pathogen.

Virulence factors

The role of such factors as toxins and extracellular proteins in nocardiosis is unclear. No virulence factors have been identified, although virulence has been correlated with alterations in the components of the cell wall. The precise role of the various cell wall molecules in virulence is unknown. *Nocardia* spp. produce superoxide dismutase and catalase, which may provide resistance to oxidative killing by phagocytes. They also produce an iron-chelating compound called *nocobactin*. A correlation has been reported between the amount of nocobactin produced by the organism and its virulence.

Clinical infections

Infection occurs by two routes: pulmonary and cutaneous. Pulmonary infection by *Nocardia* occurs from the inhalation of the organism present in dust or soil and is the most common manifestation of disease. The disease appears to be associated with impaired host defenses because most individuals with *Nocardia* infections have an underlying disease or compromised immune system. Approximately 10% of *Nocardia* infections occur in seemingly healthy patients with no obvious immune impairment. Infection with *Nocardia* spp. can be serious. Approximately 40% of the diagnoses are made at autopsy. The mortality rate is high, and patients who survive often have significant tissue damage. Disseminated infections resulting in brain abscesses have been reported.

Pulmonary infections

The most common manifestation of infection is a confluent bronchopneumonia that is usually chronic but may be acute or relapsing. The disease generally progresses more rapidly than tuberculosis, and the course is measured in months rather than years. In the acute form, which is often seen in patients with underlying immune defects, the course is a matter of weeks.

The initial lesion in the lung is often a focus of pneumonitis that advances to necrosis. The abscesses that form can extend into the tissue and coalesce with each other. Extensive tissue involvement and damage result. In contrast with some pneumonias, there is little inflammatory response or scarring, there is no encapsulation of the abscesses, and no granuloma formation occurs. Sputum is thick and purulent. In contrast with infection by the anaerobic actinomycetes, no sulfur granules (masses of filamentous organisms bound together

by calcium phosphate) develop, and no sinus tract formation occurs. Dissemination to other organs, especially the brain, may occur, with reports of involvement of virtually every organ.

Cutaneous infections

Cutaneous infection occurs after inoculation of the organism into the skin or subcutaneous tissues usually seen in the hands and feet as a result of outdoor activity. The trauma most likely is minor, such as from a thorn or wood sliver.

The infection begins as a localized subcutaneous abscess that is invasive and quite destructive of the tissues and underlying bone. These lesions are termed **actinomycotic mycetomas**. *N. brasiliensis* is the most common cause of actinomycotic mycetoma. Some species of fungi also cause mycetomas; mycetomas caused by bacteria are called *actinomycotic mycetomas*, whereas mycetomas caused by fungi are known as **eumycotic mycetomas**. Depending on the causative agent, mycetomas are characterized by swelling, draining sinuses, and granules. About one half of the mycetomas seen clinically are caused by actinomycetes, and the remaining one half are caused by fungi. As the infection progresses, burrowing sinuses open to the skin surface and drain pus. The pus may be pigmented and contain "sulfur granules" (Fig. 16.15). The granules often appear yellow or orange and have a distinct granular appearance—hence the term *sulfur granules*.

Laboratory diagnosis

Microscopy

The gram-positive, beaded, branching filaments characteristic of *Nocardia* are often seen in sputum and in exudates or aspirates from skin or abscesses. The specimen often contains coccobacillary bodies as well. The beaded appearance of *Nocardia* may be confused as chains of gram-positive cocci; however, the beads do not usually touch each other and are not as regular as cocci. Presumptive identification of *Nocardia* can be made based on observation of a filamentous, branching isolate that is partially acid fast on staining with carbolfuchsin and decolorizing with a weak acid (0.5% to 1% sulfuric acid) compared with 3% hydrogen chloride in the stain for mycobacteria.

Wet mounts can also be performed on clinical specimens. Tissue and pus from the draining sinuses are the specimens of choice for direct examination. Granules may be seen in specimens from cutaneous infection. The small granules (80 µm to 130 µm) can be visualized by separating them from the pus with an inoculating needle and then washing in sterile saline. The granules of *N. cyriacigeorgica*, *N. farcinica*, *N. brasiliensis*, and *N. otitidiscaviarum* are soft and white to cream in color. They can be crushed between two glass slides to visualize the branching and cellular morphology, which comprises gram-positive, thin (0.5 to 1.0 µm in diameter), interwoven filaments. The granules may also be used to inoculate the appropriate growth media. The granules of a eumycotic mycetoma are composed of broad, interwoven, septate hyphae that are wider (2 to 5 µm) than those of actinomycotic mycetoma.

Culture characteristics

The growth requirements of *Nocardia* spp. are not as well defined as the growth requirements of many other medically important bacteria. These organisms show an oxidative-type

Fig. 16.15 Appearance of a sulfur granule collected from draining sinus tracts. These granules contain masses of filamentous organisms with pus materials. The arrow points to eosinophilic projections (clubs) characteristic of sulfur granules from gram-positive bacteria. (Hematoxylin and eosin stain, $\times 1000$.)

metabolism, and as a genus, they use a wide variety of carbohydrates. They do not require specific growth factors as do *Haemophilus* and *Francisella* spp. *Nocardia* spp. grow well on most common nonselective laboratory media incubated at temperatures between 22° and 37° C, although 3 to 6 days or more may pass before growth is seen. *Nocardia* spp. can be recovered on simple media containing a single organic molecule as a source of carbon. Media containing antimicrobial agents used for isolating fungi should not be used because *Nocardia* spp. are susceptible to many of the agents used in these media. Selective media, such as modified Thayer-Martin agar, may enhance recovery of *Nocardia* spp. by inhibiting the growth of contaminating organisms. *Nocardia* spp. grow on nonselective buffered charcoal–yeast extract agar.

Colonies of *Nocardia* spp. might have a chalky, matte, velvety, or powdery appearance and may be white, yellow, pink, orange, peach, tan, or gray pigmented. They can have a dry, crumbly appearance similar to breadcrumbs (Fig. 16.16). Table 16.5 outlines the colony appearance and tentative identification and differentiation of aerobic actinomycetes. Examination of colonies with a dissecting microscope may reveal the presence of aerial hyphae. These macroscopic and microscopic phenotypic colony morphologies provide the first clues to the identity of the organism as belonging to the genus *Nocardia*.

Identification

An isolate showing beaded, branching filaments that are gram positive and partially acid fast should be suspected to belong to the genus *Nocardia* (see Fig. 16.14). Phenotypic tests have been used to identify clinically relevant *Nocardia* spp. Methods employed for identification include (1) substrate hydrolysis (casein, tyrosine, xanthine, and hypoxanthine); (2) other substrate and carbohydrate use, arylsulfatase, and gelatin liquefaction; (3) antimicrobial susceptibility profile; and (4) fatty acid analysis by high-performance liquid chromatography. MALDI-TOF mass spectrometry is an emerging technology for the identification of *Nocardia* species. However, the most reliable method for the identification of *Nocardia* spp. is 16S rRNA gene sequencing, which is beyond the capabilities of most clinical laboratories. If routine tests used do not result in identification, the identity can be confirmed by a

Fig. 16.16 Colony morphology of *Nocardia* on chocolate agar. (Courtesy Steve Mahlen and Amanda Harrington.)

reference laboratory with experience in identification of such organisms.

Treatment

Treatment of nocardiosis often involves drainage and surgery along with administration of antimicrobials. The organisms are resistant to penicillin but susceptible to sulfonamides, although susceptibility profiles differ among different species. Antifungal agents have no activity against *Nocardia* spp. This fact underscores the importance of laboratory diagnosis because many of the clinical manifestations of pulmonary and cutaneous infection are shared with other organisms, including fungi. *Nocardia* spp. represent a classic example of a situation in which laboratory results are essential for proper antimicrobial treatment.

Other actinomycetes

Actinomadura

There are more than 60 species in the genus *Actinomadura*. The aerobic actinomycetes of clinical importance belonging to this genus include *A. madurae* and *A. pelletieri*. They cause mycetomas that are identical to those caused by *Nocardia*. The microscopic morphology and colony morphology of *Actinomadura* spp. are very similar to those of *Nocardia* spp. (see Table 16.5), although unlike *Nocardia* spp., which are partially acid-fast, *Actinomadura* spp. are not. The organisms can be differentiated using metabolic variations. *A. madurae* is cellobiose and xylose positive, whereas *Nocardia* spp. do not produce acid from these two carbohydrates. Treatment parallels that for infections with *Nocardia*.

Streptomyces

The genus *Streptomyces* comprises a large diverse group of bacteria. *Streptomyces* spp. are primarily saprophytes found as soil inhabitants and resemble other aerobic actinomycetes with regard to morphology and the diseases they cause. *Streptomyces somaliensis* is an established human pathogen associated with actinomycotic mycetoma in many countries. Many other *Streptomyces* spp. have been implicated

Table 16.5 Gram stain morphology, colony appearance, and preliminary grouping of aerobic actinomycetes

Genus	Gram stain morphology	Colony appearance on routine agar	Partially acid fast	Nitrate	Urea	Lysozyme resistance
<i>Actinomadura</i>	Moderate, fine, inter-twining, branching with short chains or spores, fragmentation	White-to-pink pigment, mucoid, molar tooth appearance after 2 weeks' incubation; sparse aerial hyphae	–	+	–	–
<i>Gordonia</i>	Short rods	Somewhat pigmented; <i>G. sputi</i> smooth, mucoid, and adherent; <i>G. bronchialis</i> dry and raised	±	+	+	–
<i>Mycobacterium</i>	Refractile or nonvisible	Dry, buff-colored; some species are pigmented; smooth or rough colonies	Strongly acid fast	±	±	Not performed
<i>Nocardia</i>	Branching, fine, intertwining, delicate filaments with fragmentation	Extremely variable; some isolates are β -hemolytic on SBA; wrinkled; often dry, chalky white appearance to orange-tan pigment; crumbly; may produce spores from aerial hyphae	+	+	+	+
<i>Rhodococcus</i>	Diphtheroid-like with minimal branching or coccobacillary; colony growth appears as coccobacilli in "zigzag" configuration	Nonhemolytic; round; often mucoid with orange-to-red, salmon-pink pigment developing within 4–7 days; pigment may vary widely	±	±	±	±
<i>Streptomyces</i>	Extensive branching with chains and spores; does not fragment easily	Glabrous or waxy heaped colonies; variable morphology; wide range of pigmentation from cream to brown-black; white aerial hyphae	–	±	±	–
<i>Tsukamurella</i>	Mostly long bacilli that fragment; no spores or aerial hyphae	May have rhizoid edges, dry, white-to-creamy-to-orange	±	–	+	+

+, Predominantly positive; –, predominantly negative; ±, predominantly positive with some negative isolates; SBA, sheep blood agar.
 Modified from Conville P. S., & Witebsky, F. G. (2015). *Nocardia*, *Rhodococcus*, *Gordonia*, *Actinomadura*, *Streptomyces*, and other aerobic actinomycetes. In J. H. Jorgensen, et al. (Eds.), *Manual of clinical microbiology* (11th ed.). Washington, DC: ASM Press.

in different types of human infections. See Table 16.5 for a comparison of the colony morphology and metabolic characteristics of *Streptomyces* spp. with those of other aerobic actinomycetes. Isolates from this genus may need to be identified by reference laboratories.

Gordonia

Members of the genus *Gordonia* are aerobic, catalase positive, gram positive to gram variable, partially acid fast, and non-motile. They grow with mycelial forms that fragment into rod-shaped or coccoid elements—hence the term *nocardioform*. Members are distinguished from similar organisms by simple biochemical tests. They differ from rapidly growing mycobacteria by their partial acid fastness and the absence of arylsulfatase. They are distinguished from the genus *Nocardia* by their ability to reduce nitrate and the absence of mycelia.

Gordonia spp. are typically isolated from environmental sources. So far, reports of human infections are uncommon but increasing recently. In almost all cases, patients were immunosuppressed as a result of underlying diseases, and infections by *Gordonia* spp. occurred only secondarily. Most reported cases of infections were caused by *Gordonia bronchialis* and included postsurgical sternal wounds, coronary artery infection, and infection from central venous catheters. Infections by *Gordonia* spp. might be underreported because

the isolates are considered insignificant or misidentified as *Nocardia* or *Rhodococcus*. *Gordonia* spp. are susceptible to several antimicrobial agents, including many β -lactams, quinolones, aminoglycosides, macrolides, and other agents active against gram-positive organisms. In the absence of clear guidelines, treatment should be based on susceptibility test results.

Rhodococcus

Rhodococcus equi, the most common human isolate in this genus, is found in soil and causes respiratory tract infections in animals. Human infection is rare, although an increased incidence in immunosuppressed patients, particularly those with acquired immunodeficiency syndrome, has been reported. Contact with farm animals and feces is an important risk factor. Lung infections account for about 80% of human disease in immunosuppressed patients.

On Gram-stained smear, *R. equi* may demonstrate filaments, some with branching. *R. equi* may be partially acid fast or acid fast. On SBA, the colonies resemble *Klebsiella* spp. and can form a salmon-pink pigment on prolonged incubation, especially at room temperature. Biochemical identification is difficult because it does not ferment carbohydrates and shows a variable reaction to many characteristics (e.g., nitrate reduction, urease). Key features for the identification

of *Rhodococcus* is the salmon-pink pigment and Gram stain morphology showing characteristic diphtheroid gram-positive rods with traces of branching.

Tropheryma whipplei

Tropheryma whipplei is the agent of **Whipple disease**. *T. whipplei* is a facultative intracellular pathogen first identified in 1991 by using PCR from a duodenal biopsy specimen. Phylogenetic analysis has revealed that *T. whipplei* is a gram-positive actinomycete, most closely related to the genera *Rothia*, *Rhodococcus*, *Arthrobacter*, and *Dermatophilus*. *T. whipplei* has been detected in sewage and in human feces, saliva, and gastric secretions and is ubiquitous in the environment. Whipple disease was first described in 1907 by George H. Whipple and was first successfully treated in 1952 with antimicrobials. If untreated, this is a uniformly fatal disease, with typical symptoms of diarrhea, weight loss, malabsorption, arthralgia, and abdominal pain. Other organs may also be involved, including the CNS and the heart. *T. whipplei* has been associated with several cases of culture-negative endocarditis.

Despite a high incidence of human colonization, Whipple disease is rare and is seen most commonly in **White middle-age men with European heritage**. It is believed that asymptomatic carriage or a mild self-limiting gastroenteritis occurs in many children following ingestion of the organism. Cell- and humoral-mediated immunity develops, and the bacteria are cleared. In some individuals, the infection persists over a period of many years and spreads systemically, producing the classic Whipple disease.

Diagnosis is best made by microscopic examination of endoscopic biopsy specimens. The presence of characteristic periodic acid–Schiff staining is strongly suggestive of Whipple disease. In addition, rod-shaped bacteria can be observed in macrophages from infected tissues. The bacteria do not Gram stain well and are acid-fast negative. The organism has been cultivated in stable cell lines and has been adapted to an axenic culture medium supplemented with essential amino acids; however, these techniques are not easily performed in the clinical microbiology laboratory. *T. whipplei* can be identified with PCR or 16S rRNA gene sequencing. Treatment depends on disease presentation (classic Whipple disease, CNS involvement, endocarditis). *T. whipplei* is usually susceptible to trimethoprim-sulfamethoxazole, ceftriaxone and other β -lactams, doxycycline, chloramphenicol, rifampin, and aminoglycosides.

Spore-forming, nonbranching, catalase-positive bacilli

Bacillus

General characteristics

Members of the genus *Bacillus* stain gram positive or gram variable and are aerobic or facultative anaerobic bacilli that form endospores. There are more than 90 species within the genus, and all are widely distributed in the soil and the environment. Members of the genus *Bacillus* are metabolically

diverse, and some species are thermophiles that grow best at 55° C or higher. The survival of *Bacillus* spp. in nature is aided by the formation of spores that are resistant to conditions to which vegetative cells are intolerant.

Most species grow well on SBA and other commonly used enriched media but typically do not grow on Columbia colistin-naladixic acid agar. Colony characteristics differ considerably among the species and are often influenced by the type of medium used. Most species form nonpigmented colonies and are catalase positive. Members of the genus *Bacillus* can be confused with aerotolerant strains of the other primary endospore-forming genus, *Clostridium*. *Clostridium* spp. are typically catalase negative, although some strains may form trace amounts. In addition, *Bacillus* spp. form endospores aerobically and anaerobically, whereas *Clostridium* spp. form endospores anaerobically only. *Bacillus* spp. are divided into groups based on genetic identity and morphologic features. The *Bacillus cereus* group, consisting of *B. anthracis*, *B. cereus*, *B. thuringiensis*, *B. mycoides*, *B. pseudomycoides*, and *B. cytotoxicus*, among others, is the most medically relevant group. The species in the *B. cereus* group are genetically very closely related.

Many *Bacillus* spp. are commonly isolated and often regarded as laboratory contaminants. Therefore most laboratories do not identify the majority of *Bacillus* isolates to the species level. Several species are considered insect and plant pathogens, and some species are associated with human infections, including *B. anthracis* and *B. cereus*. Koch, in the development of Koch's postulates, showed that *B. anthracis* caused **anthrax** in cattle and helped prove the germ theory of disease. Historically, *B. anthracis* has been the most important member of this genus; however, anthrax is rarely reported in the United States. Because *B. anthracis* is considered to be a potential bioterrorism agent, it is important for clinical laboratories to rule out this organism when *Bacillus* spp. are isolated and to send isolates to a reference laboratory in the Laboratory Response Network (LRN) when it cannot be ruled out.

In 2016, *B. cereus* biovar *anthracis* was added to the list of potential bioterrorism agents. Currently, this biovar has only been found in African countries (including Cameroon, Côte d'Ivoire, Liberia, Democratic Republic of Congo, and Central African Republic) and is known to cause anthrax-like disease in gorillas, chimpanzees, elephants, mongooses, and other animals. To date, there have been no known cases of human infection caused by *B. cereus* biovar *anthracis*. *B. cereus* biovar *anthracis* produces all of the virulence factors that *B. anthracis* produces, including capsule, **protective antigen (PA)**, **edema factor (EF)**, and **lethal factor (LF)**.

Bacillus anthracis

Virulence factors

The virulence of *B. anthracis* depends on a glutamic acid capsule and a three-component protein exotoxin. The genes that code for the toxin and the enzymes responsible for capsule production are carried on plasmids. If a virulent isolate is repeatedly subcultured in vitro, the plasmids can be lost, and the organism becomes avirulent. The capsule, which protects the organism from phagocytosis, is a polypeptide of D-glutamic acid. This particular isomer of glutamic acid is resistant to hydrolysis by host proteolytic enzymes because it is

the “unnatural” form of the amino acid (L-glutamic acid). Although the capsule is necessary for virulence, antibodies against the capsule do not confer immunity.

Anthrax toxin consists of three proteins: PA, EF, and LF, each of which individually is nontoxic but together act synergistically to produce damaging effects. PA serves as a necessary binding molecule for EF and LF, permitting their attachment to specific receptors on the host cell’s surface. The effect of EF and LF is seen when either is combined with PA. Edema results from the combination of PA with EF, whereas death occurs when PA and LF combine. EF is an adenylate cyclase that increases the concentration of cyclic adenosine monophosphate (cAMP) in host cells. LF is a protease that kills host cells by disrupting the transduction of extracellular regulatory signals.

Clinical infections

Anthrax is a common disease in livestock worldwide when the vaccine is not used. The disease is not spread from animal to animal but rather is spread by animals feeding on plants contaminated with the spores or from contaminated soil. Humans are infected primarily as a result of accidental or occupational exposure to animals or animal products. Human anthrax in the United States is rare. In 2001, 11 cases of inhalation anthrax and 11 cases of cutaneous anthrax occurred in the United States. Investigations into these cases revealed that they were bioterrorism related, and a suspect in the case was eventually identified. Cases mostly occurred among postal workers as a result of exposure to spore-tainted material (powder in or on envelopes) sent through the mail, although the actual source remains unknown for some cases. *B. anthracis* as an agent of bioterrorism is discussed in [Chapter 30](#). From 2002 to 2019, there were nine cases of anthrax in the United States, none of which were attributed to bioterrorism events. Every year, there are outbreaks of anthrax in livestock in the United States, usually in western states in animals that were not vaccinated.

Worldwide, cases of anthrax number several thousand per year. The disease is enzootic in many parts of the world, including Africa, Central America, and South America. The largest outbreak involving primarily cutaneous anthrax occurred in Zimbabwe in the early 1980s with approximately 10,000 cases. Numerous names have been given to infections with *B. anthracis*. Most of these refer to occupational associations. Terms such as *wool sorter’s disease* and *ragpicker’s disease* were used to describe infection with the spores of *B. anthracis* as a result of handling contaminated animal fibers, hides, and other animal products. Three main forms of anthrax are recognized in humans: cutaneous, inhalation or pulmonary, and gastrointestinal. Infection results from wound contamination, inhalation, or ingestion of spores, which germinate within the host tissue. A fourth form, called *injectional anthrax*, has emerged more recently and is recognized as an additional form of clinical infection. Infection results from direct injection of spores into tissue generally during the administration of drugs of abuse.

Cutaneous anthrax

Cutaneous anthrax can occur when wounds are contaminated with anthrax spores acquired through skin cuts, abrasions, or insect bites. About 99% of anthrax cases in the world are the cutaneous type. Most commonly, cutaneous anthrax occurs on the hands, arms, neck, and head. In this form of anthrax, a

small pimple or papule appears at the site of inoculation 2 to 3 days after exposure. A ring of vesicles develops, and the vesicles coalesce to form an erythematous ring. A small dark area appears in the center of the ring and eventually ulcerates and dries, forming a depressed black necrotic central area known as an **eschar** or *black eschar*. The lesion is sometimes referred to as a *malignant pustule*, even though it is not a pustule and is not malignant. The lesion is painless and does not produce pus unless it becomes secondarily infected with a pyogenic organism. The eschar is normally 1 to 3 cm in diameter, but it may be more extensive. The eschar begins to heal after 1 to 2 weeks. The lesion dries, separates from the underlying base, and falls off, leaving a scar. Usually, the infection remains localized, but regional lymphangitis and lymphadenopathy appear. If septicemia occurs, symptoms of fever, malaise, and headache are seen. Normally, in uncomplicated cases, no systemic symptoms are present. The mortality rate of cutaneous anthrax is 20% with no treatment. However, those who are treated usually survive. Cutaneous anthrax is the most common and has the lowest mortality.

Inhalation anthrax

Inhalation anthrax, also called **wool sorter’s disease**, is acquired when spores are inhaled into the pulmonary parenchyma. The infection begins as a nonspecific illness consisting of mild fever, fatigue, and malaise 2 to 5 days after exposure to the spores. It resembles an upper respiratory tract infection, such as that seen with colds and flu. This initial, mild form of the disease lasts 2 to 3 days. It is followed by a sudden severe phase in which respiratory distress is common. The severe phase of the disease has a high mortality rate; inhalation anthrax is nearly always fatal if not treated. The respiratory problems (dyspnea, cyanosis, pleural effusion) are followed by disorientation, coma, and death. The course of the severe phase (onset of respiratory symptoms to death) may last only 24 hours. With proper treatment, approximately 55% of patients with inhalation anthrax will survive.

Gastrointestinal anthrax

Gastrointestinal anthrax occurs when the spores are inoculated into a lesion on the intestinal mucosa after ingestion of undercooked or raw meat containing *B. anthracis* spores. The symptoms of gastrointestinal anthrax include abdominal pain, nausea, anorexia, and vomiting. Bloody diarrhea can also occur. Because this form of the disease is difficult to diagnose, the fatality rate is about 50% with no treatment. Gastrointestinal anthrax accounts for less than 1% of total cases worldwide; a case of gastrointestinal anthrax occurred in the United States in 2009 involving a woman who participated in a drumming circle. The drums were made with animal hides.

Injectional anthrax

Injectional anthrax is characterized by soft tissue infection associated with “skin popping” or other forms of injection drug use and results from the direct injection of the spores into tissue. Although it was initially reported in 2000, injectional anthrax was first recognized in Scotland during a 2009 to 2010 outbreak associated with heroin. There were 47 confirmed cases and 13 deaths, and 7 cases and 5 deaths were additionally identified in England and Germany. Injectional anthrax can be associated with necrotizing fasciitis, organ failure, shock, coma, and meningitis, and it has a much

higher rate of mortality than cutaneous anthrax. Injectional anthrax soft tissue infections have not been associated with black eschar formation. Lack of eschar, severity of disease, and increased mortality rate make this form clinically distinct from the cutaneous form. To date, there have been no cases of injectional anthrax in the United States.

Complications

Approximately 5% of patients with anthrax (cutaneous, inhalation, gastrointestinal, or injectional) develop meningitis, with a greater proportion of cases occurring in the inhalation and injectional forms. The symptoms are typical of any bacterial meningitis and develop rapidly. Unconsciousness and death, if they occur, follow 1 to 6 days after initial exposure. Evaluation of cases suggests that initial therapy should be a multidrug regimen, including a fluoroquinolone and one or more additional agents with good CNS penetration. Recovery from infection appears to confer immunity.

An effective vaccine is available for individuals who are at risk for occupational exposure. This includes veterinarians, laboratorians working with *B. anthracis*, and persons in the military because of the biological warfare potential. The human vaccine is a cell-free culture filtrate of bacterial proteins adsorbed onto an aluminum salt. The vaccine was approved in 2015 by the U.S. Food and Drug Administration (FDA) for anyone who may have been exposed to anthrax. As described earlier, vaccines are also available for use in farm animals.

Laboratory diagnosis

Microscopy

B. anthracis is a large (1.0 to 1.5 μm $\times$ 3.0 to 5.0 μm), square-ended, gram-positive or gram-variable rod found singly or in chains (Fig. 16.17). When in chains, the ends of the single cells fit snugly together; this, together with the unstained central spore, gives the appearance of bamboo rods. Young cultures stain gram positive; as the cells age, or if they are under nutritional stress, they become gram variable. In Gram stain preparations of clinical samples, vegetative cells can appear with clear zones around the cells, representing the presence of a capsule. The presence of large encapsulated gram-positive rods in blood is strongly presumptive for *B. anthracis* identification. As the bacteria are subcultured, capsule production ceases. Incubation in an atmosphere containing increased CO_2 can stimulate capsule production. Spores are generally not present in clinical samples but sometimes can be seen as unstained areas within the cells. Spores can be observed with a spore stain. With this technique, vegetative cells stain red, and the spores stain green (Fig. 16.18).

Cultural characteristics

On SBA, colonies of *B. anthracis* are nonhemolytic, large (2 to 5 mm), gray, and flat with an irregular margin because of outgrowths of long, filamentous projections of bacteria that can be seen with a dissecting microscope. The term **Medusa head** has been used to describe the colony morphology of *B. anthracis*. Colonies have a tenacious consistency, holding tightly to the agar surface, and when the edges are lifted with a loop, they stand upright without support. This has been described as having the appearance or characteristic of beaten egg whites. Although *B. anthracis* is nonhemolytic on SBA, weak hemolysis may appear under areas of heavy growth

Fig. 16.17 Gram stained smear of *Bacillus* ($\times 1000$). (Courtesy Cathy Bissonette.)

Fig. 16.18 Spore stain of *Bacillus*. Vegetative cells are red; spores are green ($\times 1000$). (Courtesy Cathy Bissonette.)

after prolonged incubation; this should not be confused with β -hemolysis because many *Bacillus* spp. other than *B. anthracis* are hemolytic.

Because *B. anthracis* would typically be isolated from normally sterile sites, such as blood, lung tissue, and CSF, selective media are not usually needed for recovery. Although some strains of *B. anthracis* grow on phenylethyl alcohol (PEA) medium, growth is usually weak. The current American Society of Microbiology (ASM) sentinel level testing protocol for the presumptive identification of anthrax recommends using SBA and MacConkey (MAC) agar (or eosin-methylene blue [EMB] agar) for cutaneous, tissue, and stool specimens. For respiratory specimens, SBA, chocolate (CHOC) agar, and MAC agar (or EMB agar) are recommended, whereas for CSF cultures, SBA, CHOC agar, and broth medium, such as Tryptic soy broth (TSB), should be used.

Identification

Caution should always be used when working with an isolate suspected of being *B. anthracis*. Work should be performed in a biological safety cabinet, and the area should be disinfected when the work is completed. Approved tests that should be performed by LRN sentinel laboratories include Gram staining and colony morphology, catalase, and motility tests. Gram staining can be performed directly on clinical specimens or

on culture isolates. If the microscopic and colony morphologies of the isolate are compatible with *B. anthracis*, additional tests need to be performed, typically at an LRN reference laboratory.

B. anthracis is catalase positive and grows aerobically or anaerobically. Although *B. anthracis* ferments glucose, it fails to ferment mannitol, arabinose, or xylose. *B. anthracis* produces lecithinase; an opaque zone can be seen around colonies growing on egg-yolk agar. This species grows in high-salt (7% sodium chloride) and low pH (<6) conditions. In contrast with *B. cereus*, *B. anthracis* is generally susceptible to penicillin (10 U/mL). Characteristics important to differentiate *B. anthracis* from the closely related *B. cereus* are listed in Table 16.6.

B. anthracis is nonmotile, distinguishing it from most other members of the genus; *B. mycoides* is also nonmotile. Motility should be tested by inoculation into semi-solid medium. Capsule production by *B. anthracis* can be detected by India ink staining on blood or CSF specimens or on cells isolated in media supplemented with sodium bicarbonate, although this technique is not routinely performed by clinical laboratories.

If the laboratory cannot rule out *B. anthracis*, the isolate is sent to an LRN reference laboratory, usually a state laboratory, for confirmation. The reference laboratory is likely to perform direct fluorescent antibody assays for a cell wall polysaccharide and a capsule antigen. The presence of both antigens is confirmation for *B. anthracis*. Antimicrobial susceptibility testing is performed by reference or national laboratories. The ASM sentinel level anthrax protocol does not recommend using MALDI-TOF mass spectrometry or other automated systems for the identification of *B. anthracis* for biosafety reasons and because of the potential for misidentification. Nucleic acid amplification tests have been developed, but such applications for diagnosis and identification of *B. anthracis* are only used in LRN reference or national level laboratories.

B. cereus biovar *anthracis* strains are usually nonhemolytic on SBA, like *B. anthracis*, but are motile, unlike *B. anthracis*. The exception is goat strains from the Democratic Republic of the Congo, which are nonmotile. As described earlier, there have been no known human cases of anthrax-like disease caused by *B. cereus* biovar *anthracis* to date.

Table 16.6 Differentiation of *Bacillus anthracis* and *Bacillus cereus*

Characteristic	<i>B. anthracis</i> ^a	<i>B. cereus</i> ^a

From Turenne, C. Y., & Alexander, D. C. (2019). *Bacillus* and other aerobic endospore-forming bacteria. In K. C. Carroll, et al. (Eds.). *Manual of clinical microbiology* (12th ed., p. 468). Washington, DC: ASM Press.

Treatment

Most isolates of *B. anthracis* are susceptible to penicillin, but resistance can occur in the absence of β -lactamase production. Penicillin should not be used alone in treatment. The organism is often susceptible to many broad-spectrum antimicrobial agents, including carbapenems, tetracyclines, clindamycin, erythromycin, linezolid, fluoroquinolones, and chloramphenicol. Current recommendations for antimicrobial therapy depend on the type of anthrax and whether or not the illness is systemic. Ciprofloxacin is the primary recommended therapy in most cases, either alone or in combination with other agents. Postexposure prophylaxis recommendations for inhalational anthrax depend on the status of the exposed individual (children, nonpregnant adults, pregnant women/nursing mothers) but usually includes either ciprofloxacin or doxycycline and vaccination.

Bacillus cereus

B. cereus is a relatively common cause of food poisoning and opportunistic infections in susceptible hosts. Food poisoning caused by *B. cereus* takes two forms: diarrheal and emetic. The diarrheal syndrome, usually associated with ingestion of meat or poultry, vegetables, and pastas, is characterized by an incubation period of 8 to 16 hours. Affected individuals have abdominal pain and diarrhea. About 25% of individuals have vomiting; fever is uncommon. The average duration of the illness is 24 hours. The diarrheal form is clinically indistinguishable from diarrhea caused by *Clostridium perfringens*.

The emetic form has the predominant symptoms of nausea and vomiting 1 to 5 hours after ingestion of contaminated food. Diarrhea is present in about one third of affected individuals. This form has been associated particularly with ingestion of fried rice prepared in Asian restaurants. The average duration of the illness is 9 hours. For both the diarrheal and the emetic forms of *B. cereus* food poisoning, the illness is usually mild and self-limiting. The two forms of illness are caused by two distinct enterotoxins. The enterotoxins are compared in Table 16.7.

Culture of suspected food from a food poisoning incident may be performed to isolate and quantify *B. cereus*. If more than 10^5 *B. cereus* cells per gram of food are present and other pathogens are absent, food poisoning by this organism is confirmed. Because *B. cereus* can be found in small numbers in a significant proportion of healthy people, quantitative cultures must be done. To confirm the organism as the cause of the disease, viable counts from the stool should also be at least 10^5 cells per gram. Most food poisoning cases caused by *B. cereus* do not require antimicrobial treatment. However, treatment may be indicated in other *B. cereus* infections. In contrast with *B. anthracis*, *B. cereus* is resistant to penicillin and all of the other β -lactam antibiotics except the carbapenems. Treatment with vancomycin or clindamycin with or without an aminoglycoside has been successful.

B. cereus is similar to *B. anthracis* in many ways—morphologically and metabolically. Differentiation of the two species is outlined in Table 16.6. *B. cereus* can be grown aerobically at 37° C on SBA. A β -hemolytic frosted glass–appearing colony (Fig. 16.19) containing spore-forming, gram-positive bacilli that are motile, able to ferment salicin, and lecithinase positive is likely *B. cereus*. *B. cereus* is biochemically

Table 16.7 Comparison of enterotoxins produced by *Bacillus cereus*

Characteristic	Type of enterotoxin	
	Diarrheal	Emetic
Clinical syndrome		
Incubation period	8–16 hours	1–5 hours
Diarrhea	Very common	Fairly common
Vomiting	Occasional	Very common
Duration of illness	12–24 hours	6–24 hours
Foods implicated	Meat products, soups, vegetables, puddings, sauces	Fried or boiled rice
Enterotoxins		
Molecular weight	≈50,000	<5000
Stability to heat	–	+
Stimulation of adenylate cyclase–cAMP system in intestinal epithelial cells	+	–
cAMP, Cyclic adenosine monophosphate. Modified from Braude, A. I., et al. (Eds.). (1986). <i>Infectious diseases and medical microbiology</i> (2nd ed.). Philadelphia: Saunders.		

identical to *B. thuringiensis* except that *B. thuringiensis*, an insect pathogen, typically produces parasporal crystals that can be observed by using phase-contrast microscopy or spore staining.

B. cereus eye infections are the most common type of non-gastrointestinal infection caused by this organism; these include endophthalmitis, panophthalmitis, and keratitis with abscess formation. *B. cereus* infection in penetrating ocular trauma cases is nearly always associated with a poor visual outcome. This organism has also been documented as a cause of meningitis, septicemia, endocarditis, osteomyelitis, and many other types of infections. Although rare, these serious, nongastrointestinal infections occur more frequently in intravenous drug abusers, neonates, and immunosuppressed and postsurgical patients. In addition, there have been a few reports of *B. cereus* strains carrying the *B. anthracis* toxin genes. In these cases, *B. cereus* caused severe pneumonia clinically similar to pulmonary anthrax. In 2010 and 2011, *B. cereus* was reported in nonsterile alcohol pads used as an antiseptic measure before injections. The bacteria resulted in several fatal infections, leading to the recall of millions of cases of pads and the questioning of the use of such products. Most alcohol pads used in hospitals are sterile.

Other *Bacillus* species

Infections by other members of the genus *Bacillus* are rare. These include, but are not limited to, *B. subtilis*, *B. licheniformis*, *B. circulans* (now *Niallia circulans*), *B. pumilus*, and *B. sphaericus* (now *Lysinibacillus sphaericus*). These organisms have been reported to cause food poisoning, bacteremia, meningitis, pneumonia, and other infections. However, they are more commonly seen as contaminants.

Fig. 16.19 *Bacillus cereus* on sheep blood agar. (Courtesy Cathy Bissonette.)

POINTS TO REMEMBER

- *C. diphtheriae* causes serious disease in populations of countries where the diphtheria vaccine is not available.
- Nondiphtheria *Corynebacterium* species are opportunistic pathogens.
- *L. monocytogenes* can be differentiated from streptococci and enterococci on the basis of Gram stain morphology, catalase reaction, and motility.
- *E. rhusiopathiae* differs from *L. monocytogenes* in catalase reaction, hydrogen sulfide production, and lack of ability to grow at 4°C.
- *A. haemolyticum* can be differentiated from other non-spore-forming gram-positive bacilli and β -hemolytic streptococci by Gram stain morphology, catalase activity, and the CAMP inhibition reaction or reverse CAMP test.
- *G. vaginalis* is part of the normal biota of the urogenital tract but might play a role in BV. It is weakly β -hemolytic on HBT agar and stains as a gram-variable rod.
- Aerobic actinomycetes are generally soil inhabitants. They are weak pathogens sometimes associated with wounds after traumatic implantation into subcutaneous tissue.
- *Nocardia* spp. are gram-positive, filamentous organisms that can grow on nutritionally simple media and are partially acid fast.
- To provide accurate identification and speciation of actinomycetes, 16S rRNA gene sequencing is often required; however, this is unavailable in most clinical laboratories.
- Members of the genus *Bacillus* are aerobic, gram-positive, catalase-positive, rod-shaped organisms that form endospores.
- Many aerobic, gram-positive spore-forming bacilli are rarely associated with human infections. The most important pathogen in this group is *B. anthracis*.
- *B. anthracis* is generally susceptible to penicillin and is nonmotile and nonhemolytic on SBA, features important to differentiate the organism from *B. cereus*.
- *B. cereus* is a common cause of food poisoning and opportunistic infections. Food poisoning caused by *B. cereus* occurs in two forms: diarrheal and emetic.

LEARNING ASSESSMENT QUESTIONS

1. An isolate with the appropriate colony and microscopic morphology may be suspected to be *Bacillus anthracis* if it has which of the following characteristics?
 - a. β -Hemolytic on SBA
 - b. Nonmotile
 - c. Catalase negative
 - d. Gram negative, non-spore forming
2. An aerobic, gram-positive, spore-forming bacillus was isolated from raw vegetables that were associated with an outbreak of gastroenteritis. The organism produced β -hemolysis, was catalase positive, and was motile. Which of the following is the most likely organism?
 - a. *Bacillus anthracis*
 - b. *Nocardia nova*
 - c. *Bacillus cereus*
 - d. *Tsukamurella* spp.
3. *Bacillus cereus* is most noted for causing which illness?
 - a. Food poisoning
 - b. Meningitis
 - c. Sexually transmitted disease
 - d. Urinary tract infection
4. Which forms of infection are caused by *Bacillus anthracis*?
 - a. Inhalation
 - b. Gastrointestinal
 - c. Cutaneous
 - d. All of the above
5. The functionality of lethal factor requires the presence of which other protein from *Bacillus anthracis* to form an active toxin?
 - a. Cyclic adenosine monophosphate
 - b. Edema factor
 - c. D-Glutamic acid
 - d. Protective antigen
6. Describe the appearance of spore-forming bacteria seen with the spore stain.
7. How do *Corynebacterium* species often appear on Gram-stained smears?
 - a. Pleomorphic, gram-positive, club-shaped bacilli that appear in palisades or in V and L formations
 - b. Branching gram-positive bacilli that appear as fine, intertwining, delicate filaments
 - c. Short, thin gram-positive bacilli that appear in chains
 - d. Large square-ended, gram-positive or gram-variable bacilli in chains where the ends of the single cells fit snugly together
8. Biochemical tests performed on a gram-positive bacillus were consistent with *Corynebacterium diphtheriae*. Which definitive test should the laboratory scientist perform next?
 - a. Prepare a smear of the isolate for Gram stain, and observe it for its pleomorphic morphology.
 - b. Prepare a methylene blue stain, and examine it for metachromatic granules.
 - c. Perform an Elek test to determine whether the organism produces exotoxin.
 - d. Subculture the organism to cystine-tellurite blood agar, and examine it for black colonies.
9. Why is diphtheria uncommon in the United States?
 - a. Elimination of the insect vector
 - b. Vaccination of the animal reservoir
 - c. Routine use of an effective human vaccine
 - d. Elimination of the bacteria with aggressive antimicrobial therapy
10. True infections with nondiphtheria *Corynebacterium* spp., such as *C. jeikeium* or *C. striatum*, often occur in immunocompromised patients or patients who have had which of the following?
 - a. Insertion of hardware or prosthetic devices
 - b. Coronary artery bypass surgery
 - c. Vitamin B₁₂ deficiency
 - d. A lengthy hospital stay
11. When recovered from urine samples, which test can help differentiate which clinically significant *Corynebacterium* spp.?
 - a. Gelatin hydrolysis; *C. ulcerans*
 - b. Reverse CAMP; *C. pseudotuberculosis*
 - c. Alkaline phosphatase; *C. amycolatum*
 - d. Urease; *C. urealyticum*
12. A newborn female patient becomes febrile and will not feed for about an hour after birth. A gram-positive rod is recovered from blood cultures from the newborn. The isolate has the following characteristics:
Weakly β -hemolytic on SBA
Gram-positive bacilli, no spores observed
Catalase positive
Hydrogen sulfide negative
Motile at room temperature
What is the most likely identity of the isolate?
 - a. *Erysipelothrix rhusiopathiae*
 - b. *Listeria monocytogenes*
 - c. *Corynebacterium ureilyticum*
 - d. *Gardnerella vaginalis*
13. A commercial fisherman with red sores on his hands was seen by his physician. Biopsy and culture of one of the lesions grew an organism with the following characteristics:
Nonhemolytic on SBA
Gram-positive bacilli, no spores observed
Catalase negative
Hydrogen sulfide production positive
Growth in gelatin resembled a test-tube brush
What is the most likely identification?
 - a. *Rhodococcus equi*
 - b. *Listeria monocytogenes*
 - c. *Lactobacillus acidophilus*
 - d. *Erysipelothrix rhusiopathiae*
14. A 42-year-old male patient from Guatemala cut his bare feet on thorns while walking. A subcutaneous abscess developed, and when the patient is seen by a physician, his foot is swollen. When the physician presses the wound, purulence is expressed along with some soft, white granules. A filamentous organism that is partially acid fast is recovered from the granules. This is most likely an _____ mycetoma caused by _____.
 - a. Actinomycotic; *Pseudallescheria boydii*
 - b. Actinomycotic; *Nocardia brasiliensis*
 - c. Eumycotic; *Madurella mycetomatis*
 - d. Eumycotic; *Gordonia bronchialis*

15. Which other organisms can give similar clinical and laboratory findings as those for *Listeria monocytogenes*? How are these organisms differentiated from *L. monocytogenes*?
16. A 17-year-old male patient presented to an emergency department with a history of multiple episodes of febrile pharyngitis followed in 10 to 14 days by extensive desquamation of his hands and feet. The recurrences have followed several courses of antimicrobial therapy, including amoxicillin and cephalosporins. Rapid group A streptococci screens and cultures have been consistently negative for *Streptococcus pyogenes*. A specimen with a request for an alternative agent is submitted to a reference laboratory, and the following results are observed:
SBA: small, slightly hemolytic colony, which at 48 hours is a dark spot sunken in the agar
Catalase negative
Nitrate negative
Reverse CAMP test positive
The patient was subsequently treated with erythromycin, and he recovered. What was the etiologic agent?
a. *Corynebacterium diphtheriae*
b. *Arcanobacterium haemolyticum*
c. *Listeria monocytogenes*
d. *Rhodococcus equi*
17. A 57-year-old male patient from New York City presents to the emergency department with diarrhea, arthralgia, abdominal pain, malabsorption, and weight loss of 10 lb (4.5 kg) over the past month. A duodenal biopsy is performed, but no infectious agent is recovered on culture media. However, on a Gram-stained smear, a gram-positive rod is observed in macrophages in the biopsy tissue. The organism is identified by 16S rRNA gene sequencing. What is the most likely identity of this organism?
a. *Bacillus anthracis*
b. *Nocardia asteroides*
c. *Tropheryma whippelii*
d. *Erysipelothrix rhusiopathiae*

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the general characteristics of the genus *Neisseria*.
2. List the major pathogens within the genus *Neisseria*.
3. Describe the major virulence factors of the pathogenic *Neisseria* species and their function.
4. Compare gonorrhea in male and female patients, including potential complications of asymptomatic infections in women.
5. Discuss the pathology of ophthalmia neonatorum and how it can be prevented.
6. Determine the optimal specimen collection and transport methods for isolating *Neisseria gonorrhoeae*.

7. Compare the usefulness of direct Gram stain in the diagnosis of gonorrhea in men and women.
8. Describe nonselective and selective media for the isolation of *N. gonorrhoeae* and *Neisseria meningitidis*.
9. Summarize the culture requirements for the isolation of *N. gonorrhoeae* and *N. meningitidis*.
10. Discuss the tests used in identification of *N. gonorrhoeae* and *N. meningitidis* in cultures, distinguishing between presumptive tests and definitive methods.
11. Justify the use of nucleic acid amplification tests for the detection of *N. gonorrhoeae*.
12. Discuss modes of antimicrobial resistance in *N. gonorrhoeae* isolates and current recommendations for antimicrobial therapy.
13. Describe the pathogenesis of clinical infections caused by *N. meningitidis*.
14. Identify the high-risk groups for acquiring *N. meningitidis* infection.
15. Justify the use of the meningococcal vaccine in various populations.
16. Describe the specimens for the recovery of *N. meningitidis*.
17. Discuss the clinical significance of *Moraxella catarrhalis* in children and adults.
18. Summarize the laboratory features of *M. catarrhalis*, including specimens, media, colony morphology, and identification tests.
19. Characterize the commensal *Neisseria* spp., and differentiate it from the pathogenic *Neisseria* spp.

KEY TERMS

Capnophilic
Fitz-Hugh–Curtis syndrome
Gonorrhea
Lipooligosaccharide (LOS)
Ophthalmia neonatorum
Pelvic inflammatory disease

Penicillinase-producing *Neisseria gonorrhoeae* (PPNG)
Waterhouse-Friderichsen syndrome

Case in point

An 18-year-old sexually active college student on the women's gymnastics team visited student health services complaining of pain, redness, and swelling of both wrist joints and the left elbow. She gave a history of casual, unprotected sexual intercourse with "three or four" men during the past 4 months. She denied any vaginal discharge or abdominal pain but recalled having had a rash recently on both her arms. An aspirate from the left wrist was sent to the laboratory for culture and Gram stain. Direct Gram-stained smear of the aspirate showed the following: "Many polymorphonuclear white blood cells, rare intracellular and extracellular gram-negative diplococci seen." At 24 hours, many small, tan colonies were visible on chocolate (CHOC) agar, but there was no growth on sheep blood agar (SBA), the Centers for Disease Control and Prevention (CDC) anaerobic blood agar, or MacConkey agar. The organism was identified according to routine laboratory protocol.

Issues to consider

After reading the patient's case history, consider:

- The identity of the organism causing the patient's infection

- Risk factors for acquisition of the organism
- Types and consequences of sequelae of untreated primary infection in female and male patients
- Importance of definitive identification of the microorganism

The family Neisseriaceae contains the genus *Neisseria* as well as *Kingella*, *Eikenella*, *Simonsiella*, *Allysiella*, and several other genera. *Moraxella catarrhalis* is in the family Moraxellaceae with other *Moraxella* spp., *Acinetobacter*, *Psychrobacter*, and several other genera. *M. catarrhalis* is included in this chapter because its cellular morphology resembles the morphology of *Neisseria*. Characteristics of the family Neisseriaceae and differential characteristics of these genera are shown in Fig. 17.1. Currently, the genus *Neisseria* contains approximately 40 species; about 17 species and biovars can be isolated from humans. This chapter discusses the *Neisseria* spp. and the morphologically and biochemically similar *M. catarrhalis*. The genera *Eikenella* and *Kingella* are discussed in Chapter 18.

*Normal oral biota of dogs, wounds from dog bites. **May cause opportunistic infections in human hosts.

Fig. 17.1 Characteristics of the family Neisseriaceae. *Moraxella catarrhalis*, although morphologically and biochemically similar to *Neisseria* spp., is not a member of the family Neisseriaceae; therefore it is not included here.

General characteristics

Most *Neisseria* spp. are aerobic, nonmotile, non-spore-forming, gram-negative diplococci. *Neisseria elongata*, *Neisseria weaveri*, and *Neisseria bacilliformis* are known exceptions, being rod shaped. All species are cytochrome oxidase and catalase positive except for *N. elongata* subsp. *nitroreducens* and *N. bacilliformis*, which are catalase negative. Many *Neisseria* spp. are capnophilic, requiring carbon dioxide (CO₂) for growth, and have optimal growth in a humid atmosphere. They can grow anaerobically if alternative electron acceptors (e.g., nitrites) are available. The natural habitats of *Neisseria* spp. are the mucous membranes of the respiratory and urogenital tracts of various animals. Table 17.1 shows the pathogenicity and host range of *Neisseria* spp. and *M. catarrhalis*.

Neisseria gonorrhoeae (often called gonococci) and *Neisseria meningitidis* (meningococci) are the primary human pathogens of the genus. *N. gonorrhoeae* is not considered part of the normal biota and is always pathogenic. *N. meningitidis* may be found as a commensal inhabitant of the upper respiratory tract of carriers, but it can also become an invasive pathogen. Pathogenic *Neisseria* spp. are fastidious organisms, requiring enriched media for optimal recovery, and are sensitive to unfavorable environmental conditions. Both *N. gonorrhoeae* and *N. meningitidis* require iron for growth. They compete with their human host by binding human transferrin to specific surface receptors. Their ability to bind transferrin may be a primary reason that they are strict human pathogens. *N. weaveri*, which is a commensal in the upper respiratory tract

of dogs, has been isolated from dog bites in humans. All other *Neisseria* spp. are considered opportunistic pathogens. These opportunists must be recognized and differentiated from *N. gonorrhoeae* and *N. meningitidis* in isolates from clinical specimens.

Pathogenic *Neisseria* species

Virulence factors

Pathogenic *Neisseria* spp. have several characteristics that contribute to their virulence, including the following:

- Receptors for human transferrin
- Capsule (*N. meningitidis*)
- Pili (fimbriae)
- Cell membrane proteins
- Lipooligosaccharide (LOS) or endotoxin; lipid A moiety and core LOS of lower molecular weight that differentiates it from the lipopolysaccharide found in most gram-negative bacilli and is loosely attached to the underlying peptidoglycan
- Immunoglobulin A (IgA) protease that cleaves IgA on mucosal surfaces

N. gonorrhoeae is divided into five morphologically distinct colony types. Types T1 to T5 are based on the presence or absence of pili, fine hairlike projections that are important in the initial attachment of the organism to host tissues. Pili also inhibit phagocytosis of the organism by neutrophils and aid in the exchange of genetic material between cells. Types T1 and T2, which possess pili, are virulent forms, whereas types T3 to T5 are devoid of pili and are avirulent. Piliated organisms usually predominate when first isolated from uncomplicated urogenital tract infections, but on subculture, pili are lost, and colony types T3 to T5 appear.

The cell outer membrane proteins I, II, and III and LOS not only serve as protective devices of the organism but are also important in antigenic variation. *N. meningitidis* possesses a polysaccharide capsule that is antiphagocytic and serves as an important virulence factor. Twelve serotypes of capsular antigens have been identified. The LOS endotoxin is a major in vivo virulence factor that mediates damage to body tissues and elicits an inflammatory response. During periods of rapid growth, the organism releases outer membrane fragments called blebs, which contain LOS. The major outer membrane porin protein (Por), or protein I, forms channels for nutrients to pass into and waste products to exit the cell. They are coded for by two genes: *porA* and *porB*. Both genes are expressed in *N. meningitidis*, but only *porB* is expressed in *N. gonorrhoeae*. *porB* is also protective against the host's inflammatory response and serum complement-mediated killing.

Protein II (Opa, for opacity) is a group of proteins that facilitate the adherence to phagocytic and epithelial cells. Protein III (reduction modified protein) blocks host serum bactericidal (IgG) action against the organism. A schematic diagram of the cellular structure of pathogenic *Neisseria* is shown in Fig. 17.2.

Table 17.1 Pathogenicity and host range for species of *Neisseria* and *Moraxella catarrhalis*

Species	Pathogenicity	Infected host
<i>N. gonorrhoeae</i>	Primary pathogen	Humans only
<i>N. meningitidis</i>	Primary pathogen	Humans only
<i>N. lactamica</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. sicca</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. subflava</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. mucosa</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. flavescens</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. cinerea</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. polysaccharea</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. elongata</i>	Opportunistic pathogen	Warm-blooded animals
<i>N. bacilliformis</i>	Opportunistic pathogen	Warm-blooded animals
<i>M. catarrhalis</i>	Opportunistic pathogen	Humans only

Fig. 17.2 Cellular structure of the cell wall of pathogenic *Neisseria* spp.

Neisseria gonorrhoeae

Humans are the only natural host for *N. gonorrhoeae*, the agent of the sexually transmitted disease **gonorrhea**. Gonorrhea is an acute pyogenic infection of nonciliated columnar and transitional epithelium; infection can be established at any site where these cells are found. Gonococcal infections are mostly acquired through sexual contact and occur primarily in the urethra, endocervix, anal canal, pharynx, and conjunctiva. Disseminated infections from the primary site may also occur, as seen in the Case in Point.

The first use of the term *gonorrhea*, meaning a “flow of seed,” was in the second century when the urethral discharge was mistaken for semen. For centuries thereafter, the diseases syphilis and gonorrhea were confused because the two were often present together in the same individual. In 1530, it was thought that gonorrhea was an early symptom of syphilis.

The issue was further confused in 1767 because of a classic blunder by a physician who inoculated himself intentionally with pus from a patient with symptoms of gonorrhea. The pus gave the physician syphilis instead. Gonorrhea was also called *the clap*, from the French word *clapoir* meaning “brothel.”

Epidemiology

N. gonorrhoeae infections are most commonly transmitted through **sexual contact**. The primary reservoir is the **asymptomatic carrier**. In the United States, gonorrhea is a reportable disease nationally; all culture-confirmed cases must be reported to state health laboratories. Gonorrhea is second to *Chlamydia trachomatis* in the number of confirmed sexually transmitted bacterial infections in the United States. However, human papillomavirus, a nonreportable infectious agent, is estimated to be the most common cause of sexually transmitted diseases in the United States. There were 677,769 cases of gonorrhea reported in 2020, an increase of 45% from 2016. Actual numbers of infected individuals are probably much higher than reported because of a large reservoir of asymptomatic carriers and other unreported cases. Sexually active teens and young adults have the highest rates of infection. Most cases in both men and women are seen between **20 and 24 years of age**. In the United States, the highest rates are seen in high-density, urban areas, where individuals are more likely to have multiple partners and unprotected sexual intercourse.

Clinical infections

Gonorrhea has a short incubation period of approximately 2 to 7 days. In men, acute urethritis, usually resulting in purulent discharge and dysuria (painful urination), are the most common manifestations. Asymptomatic gonococcal infection in men is uncommon; up to 10% of cases are asymptomatic. *N. gonorrhoeae* strains with a nutritional requirement for **arginine, hypoxanthine, and uracil (AHU)** are often isolated from asymptomatic men. Complications in male patients include ascending infections, such as prostatitis and epididymitis.

The endocervix is the most common site of infection in women. Symptoms of infection, when present, include dysuria, cervical discharge, and lower abdominal pain. However, 50% of cases in women may be asymptomatic, leading to complications, such as **pelvic inflammatory disease**, which may cause sterility, ectopic pregnancy, or perihepatitis (**Fitz-Hugh–Curtis syndrome**).

Blood borne dissemination of *N. gonorrhoeae* occurs in less than 1% of all infections, resulting in purulent arthritis and rarely septicemia. Fever and a rash on the extremities can also be present. Most disseminated gonococcal infections are attributed to the AHU strains and occur in women. Because *N. gonorrhoeae* is inhibited by **sodium polyanethol sulfonate (SPS)**, the anticoagulant in blood culture media, it might not be recovered from blood cultures. **Gelatin can be added to the media to neutralize the effects of SPS.**

Other conditions associated with *N. gonorrhoeae* include anorectal and oropharyngeal infections. Infections in these sites are more common in men who have sex with men but can also occur in women. Most of these infections are asymptomatic or have nonspecific symptoms. **Pharyngitis is the**

chief complaint in symptomatic oropharyngeal infections, whereas discharge, rectal pain, or bloody stools may be seen in rectal gonorrhea. Approximately 30% to 60% of women with genital gonorrhea have concurrent rectal infection.

Newborns can acquire *ophthalmia neonatorum*, a gonococcal eye infection, during vaginal delivery through an infected birth canal. This condition, which can result in blindness if not treated immediately, is rare in the United States because application of antimicrobial eye drops, generally erythromycin, at birth to every infant is legally required. Ocular infections can occur in adults because of self-inoculation of the eye with infected genital secretions or, rarely, as a result of a laboratory accident.

Case check 17.1

The most common method for acquisition of *N. gonorrhoeae* infection is sexual contact. The endocervix is the most common site of infection in women; however, 50% of women are asymptomatic. The Case in Point demonstrates the risk factors for acquiring gonorrhea and, more importantly, the consequences of the sequelae of untreated infections in women. The patient had unprotected sexual intercourse with multiple partners. Because she did not have genital symptoms of gonorrhea, the organism went undetected, and *N. gonorrhoeae* infection was disseminated, resulting in septic arthritis. Septic arthritis in a patient of this age is rare, and when it occurs, the laboratory should consider *N. gonorrhoeae* as a potential causative agent.

Laboratory diagnosis

Specimen collection and transport

Specimens collected for the recovery of *N. gonorrhoeae* may be taken from the **genital tract or other sites, such as the rectum, pharynx, and joint fluid**. The laboratory should be notified when cultures for *N. gonorrhoeae* from sites other than the genital tract are requested because normal laboratory protocols for such specimens would likely not recover the organism.

The specimen of choice for genital infections in men is the urethra and in women is the endocervix. In men, purulent discharge can be collected directly onto a swab for culture. When no apparent discharge is present, the swab is inserted up to 2 cm into the anterior urethra and slowly rotated to collect material. Swabs for rectal culture should be inserted 4 to 5 cm into the anal canal. Disinfectants should be avoided in preparing the patient for collection of the specimen.

Calcium alginate and cotton swabs are inhibitory to *N. gonorrhoeae*, so Dacron or rayon swabs are preferred. Because *N. gonorrhoeae* is extremely susceptible to drying and temperature changes, direct plating of the specimen to gonococcal-selective media gives optimal results. Several commercial transport systems, such as James E. Martin Biological Environmental Chamber (JEMBEC) plates (Becton Dickinson Diagnostics, Sparks, MD) (Fig. 17.3), Gono-Pak (Becton Dickinson Diagnostics), and Transgrow (Hardy Diagnostics, Santa Maria, CA), allow direct plating in the clinical setting. These products contain selective media and a CO₂ atmosphere to provide optimal conditions until the specimen reaches the laboratory. The swab containing the specimen should be rolled in a Z pattern on the medium. On receipt in the laboratory, the media can be cross-streaked with a loop to

Fig. 17.3 Growth of *Neisseria gonorrhoeae* after 24 hours on a James E. Martin Biological Environmental Chamber (JEMBEC) plate inoculated in a characteristic Z pattern.

facilitate growth of isolated colonies. When direct plating is not possible, inoculated swabs should be placed in a transport system, such as Amies medium with charcoal; transported to the laboratory promptly; and plated within 6 hours of collection. **Do not refrigerate specimens for the recovery of *N. gonorrhoeae*.**

Direct microscopic examination

Smears for direct Gram stain should be prepared from urogenital specimens. Gram stain is not recommended for pharyngeal specimens because commensal *Neisseria* spp. can be present. The demonstration of gram-negative intracellular diplococci from the urethral discharge of a symptomatic male correlates at a rate of 89% with culture and is evidence of gonococcal infection. The gonococci are in pairs with adjacent sides flattened, giving them a kidney shape (Fig. 17.4A). Many times, avirulent forms (lacking pili) of the organism are seen as extracellular, gram-negative diplococci in the direct smear of the clinical specimen.

Because women have vaginal commensal microbiota that resembles gonococci, direct Gram stain correlates in only 50% to 70% of cases with culture. Direct Gram stain may be helpful in a symptomatic woman with discharge, but culture is necessary for confirmation. Gram stain with more than five polymorphonuclear neutrophils per high-power field but no bacteria (see Fig. 17.4B) suggests nongonococcal urethritis with other organisms, such as *C. trachomatis* or *Ureaplasma urealyticum*.

Culture

The medium of choice for cultivation of *N. gonorrhoeae* is CHOC agar. Typically, *N. gonorrhoeae* is described as an organism that does not grow on SBA. In recent years, however, some strains will grow, although slowly if incubated in an atmosphere of increased CO₂. It is not certain if this is caused by a change in the strains or in the increased enrichment of commercially prepared SBA. Because CHOC agar supports the growth of many organisms found as commensals in specimens collected for the recovery of gonococci, a selective medium is necessary. Commonly used selective media are described in Table 17.2. **All of these media contain vancomycin and colistin to inhibit gram-positive and**

Fig. 17.4 **A**, Direct Gram-stained smear of male urethral discharge showing intracellular and extracellular gram-negative diplococci (arrows), which is diagnostic of *Neisseria gonorrhoeae* (×1000). **B**, Direct smear with more than five polymorphonuclear neutrophils per high-power field but no bacteria may suggest nongonococcal urethritis (×1000).

gram-negative bacteria, along with an antifungal agent to suppress the growth of yeast. Trimethoprim is used in most of these media to prevent growth of the swarming of *Proteus* spp. To recover vancomycin-sensitive strains of gonococci, many laboratories include a CHOC agar plate as a primary plating medium. Several other bacteria grow on selective gonococcal media, including *Acinetobacter* spp., *Capnocytophaga* spp., and *Kingella denitrificans*. These isolates can be differentiated from *N. gonorrhoeae* by the oxidase and catalase tests. All specimens received in the laboratory for recovery of *Neisseria* spp. should be held at room temperature and plated as soon as possible. Because *Neisseria* spp. are susceptible to cold temperatures, media should be warmed to room temperature before inoculation.

Incubation

Inoculated plates should be incubated at 35°C in a 3% to 5% CO₂ atmosphere. Incubation is accomplished by using a CO₂ incubator, a CO₂ generating pouch, or a candle extinction jar. Plates are put into a large glass jar, where a lit candle is added, and the lid is closed. The candle burns until the oxygen concentration decreases to the point that the flame is extinguished. Candle jars obtain a CO₂ of about 3%. Scented or colored candles may be inhibitory to the gonococci, so only white, unscented wax candles are used in the candle extinction jar. Sufficient humidity is provided by the moisture evaporating from the media in a closed jar. Most microbiology laboratories use CO₂ incubators that are automatically humidified, or a pan of water can be placed in the bottom. Cultures are examined daily for growth and held for 72 hours.

Presumptive identification

Colony morphology

Colonies of *N. gonorrhoeae* on CHOC agar or selective agars are small, gray to tan in color, translucent, and raised after 24 to 48 hours of incubation (Fig. 17.5). As noted previously, five colony types of *N. gonorrhoeae* have been described: T1

Fig. 17.5 *Neisseria gonorrhoeae* colony morphology after 24 hours of growth on Modified Thayer-Martin (MTM) agar.

and T2 have pili and are considered virulent; these colonies are smaller and raised, and they appear bright in reflected light. Types T3 to T5 do not have pili and usually grow as larger, flatter colonies. AHU strains produce smaller colonies and grow more slowly; they are often more difficult to identify with biochemical methods. The gonococci can produce autolytic enzymes that may make the isolate nonviable on prolonged incubation. A fresh subculture should be used for identification tests.

Microscopic morphology

Gram stain must be performed on all suspected *N. gonorrhoeae* isolates to verify the appearance of gram-negative diplococci. Some gram-negative rods, such as *Kingella* and *Acinetobacter* spp., are occasionally able to grow on gonococcal selective media. To differentiate these from gram-negative diplococci, the organism can be streaked to a plate with a 10-unit penicillin disk added (Fig. 17.6). After growth, colonies at the edge of the zone of inhibition are taken and Gram-stained to visualize the morphology.

Oxidase test

The oxidase test must be done on all suspected isolates of *N. gonorrhoeae*. In the filter paper method, oxidase reagent (1% dimethyl-*p*-phenylenediamine dihydrochloride or tetramethyl-*p*-phenylenediamine dihydrochloride) is placed on filter paper, and a colony from the plate is rubbed onto the reagent with an applicator stick or a non-nichrome loop. In a positive reaction on a fresh isolate, a purple color should develop within 10 seconds (Fig. 17.7A). Alternatively, the oxidase reagent may be dropped directly onto a colony. In a positive reaction, the colony turns deep purple to black (see Fig. 17.7B). Although the direct plate method is convenient, the reagent renders organisms nonviable, so if subculture is needed, it must be done before adding the reagent. Commercial oxidase strips are also available.

Definitive identification

Other oxidase-positive, gram-negative diplococci, such as *Neisseria cinerea*, *N. meningitidis*, and *M. catarrhalis*, can grow on selective media from sites where *N. gonorrhoeae* is

Fig. 17.6 A, To differentiate some gram-negative rods from gram-negative diplococci, the organism can be streaked to a plate, and a 10-unit penicillin disk can be added. expected. These organisms would be incorrectly reported as *N. gonorrhoeae* if no further identification was performed. Many different methods are available for the identification of *Neisseria* and *Moraxella* spp. or for confirmation only of *N. gonorrhoeae* isolates. See Table 17.3 for a description of testing methods. The selection of a particular method depends on the demographic profile of patients, sensitivity and specificity of the method with low-prevalence or high-prevalence groups, cost of materials to perform procedure, time, and number of tests performed.

Carbohydrate utilization

The traditional method for the identification of *Neisseria* spp. was carbohydrate utilization in cystine trypticase agar (CTA) containing 1% of the individual carbohydrate and phenol red as a pH indicator. If the organism uses the particular carbohydrate, acid, characterized by a yellow color, is produced in 24 to 72 hours. *N. gonorrhoeae* is positive for glucose only. Many problems are associated with this method, however, and it has been replaced by rapid, more accurate tests (see Table 17.3).

The rapid carbohydrate degradation tests require pure cultures but can be read in 2 to 4 hours, rather than the 24 to 72 hours needed for the CTA carbohydrate test. These rapid tests also detect acid production from various carbohydrates, but they are based on the presence of preformed enzymes

for carbohydrate utilization rather than on bacterial growth. Problems noted with these methods include:

- Weak acid production from glucose by certain strains of *N. gonorrhoeae*
- Misidentification of sucrose-negative strains of *Neisseria subflava* as *N. meningitidis*
- Strains of *N. cinerea* that give positive glucose reactions

Chromogenic substrates

Chromogenic substrate methods, such as the Gonocheck II (EY Laboratories, San Mateo, CA), detect enzymes that hydrolyze colorless substrates and produce colored end products. Only strains that are isolated on selective media should be tested. The advantage of these tests is the identification of strains of *Neisseria* spp. with aberrant carbohydrate utilization. Problems noted with these tests include misidentification of nonpathogenic species, such as *N. cinerea*, *Neisseria sicca*, *N. subflava*, and *N. mucosa*, as *N. gonorrhoeae* or *N. meningitidis*.

Multitest methods

The multitest conventional-chromogenic enzyme methods combine enzyme substrate tests with other biochemical tests and allow for identification of strains isolated on selective or nonselective media. These tests can also identify

other genera, such as *Haemophilus*. Characteristics of clinically significant species of *Neisseria*, *Moraxella*, and *Kingella* are listed in Table 17.4. Key differentiating reactions of the major pathogens include use of glucose only by *N. gonorrhoeae*, whereas *N. meningitidis* uses glucose and maltose. *M. catarrhalis* is asaccharolytic but, in contrast with *Neisseria* spp., is deoxyribonuclease (DNase) and butyrate esterase positive.

Immunologic assays

Immunologic methods employ monoclonal antibodies against gonococcal protein I for the identification of *N. gonorrhoeae*. These methods do not require pure or viable organisms and can be done from the primary plates. However, they are not approved for use on clinical specimens. Immunologic methods include coagglutination and fluorescent antibody testing. Coagglutination tests use monoclonal antibodies directed against *N. gonorrhoeae* attached to killed *Staphylococcus aureus* cells; agglutination is a positive reaction. Sensitivity of the assays is generally high, but false-positive results because of cross-reaction with *N. cinerea*, *N. lactamica*, and *N. meningitidis* have been reported.

Matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry

Matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry is an emerging technology that identifies infectious pathogens by defining unique protein signatures of the organism (see Chapter 11). An isolated colony is ionized, resulting in vaporization of the proteins. The proteins are separated based on size and charge in an electric field, resulting in a unique spectral signature. The use of MALDI-TOF mass spectrometry has improved microbiology testing by allowing for identification of a pathogen in minutes. However, identification of closely related species of organisms can be challenging. Studies indicate that the identification of *N. gonorrhoeae* by MALDI-TOF mass spectrometry is highly accurate.

Nucleic acid amplification tests

Nucleic acid amplification tests (NAATs) are the preferred assays for the detection of *N. gonorrhoeae* in clinical specimens because of increased sensitivity, specificity, and ability to test with a noninvasive urine specimen. NAATs amplify a specific nucleic acid sequence (e.g., polymerase chain reaction) before

detecting the target sequence with a probe. Other methods rely on an amplified signal after a specific probe binds to the target sequence. NAATs are extremely sensitive and do not require viable organisms. Because urine can be used in these procedures, self-collection of the specimen is possible, and pelvic examination or intraurethral swabs are not required. First-morning voided urine from males is equivalent to or better than urethral swabs. In women, vaginal swabs have been demonstrated to be as sensitive as cervical swabs. First-morning voided urine samples from women can be used for screening, but they have been shown to detect up to 10% fewer cases compared with vaginal and cervical swabs. NAATs have the additional advantage of being less sensitive to transport and storage conditions compared with culture. NAATs can also detect both *N. gonorrhoeae* and *C. trachomatis* in the same specimen (Table 17.5).

In some situations, a NAAT is not recommended. In cases of child sexual assault involving boys and in extragenital infections (i.e., rectal, oropharyngeal) in prepubescent girls, culture is recommended because data are insufficient to recommend nonculture methods. NAATs can be used for testing vaginal or urine specimens from young girls, but culture is the preferred method for testing urethral specimens from boys or extragenital specimens from boys and girls. Culture is the only method to monitor the effectiveness of treatment because NAATs are not approved for use as a test of cure. Culture for *N. gonorrhoeae* is necessary to monitor antimicrobial resistance.

Antimicrobial resistance

In the United States, almost all strains of *N. gonorrhoeae* were previously susceptible to penicillin. In 1976, the first plasmid-mediated **penicillinase-producing *Neisseria gonorrhoeae* (PPNG)** strains were isolated, largely imported from Southeast Asia or Africa. By 1980, more than one half of the reported PPNG cases were of domestic origin. In addition to plasmid-mediated penicillin resistance, in which the organism acquires a plasmid with genes for β -lactamase production, *N. gonorrhoeae* can exhibit **chromosome-mediated penicillin resistance (PenR)**, which was initially noted in the United States in 1983. These isolates are β -lactamase negative. Resistance in these strains results from a combination of mutations at several chromosomal loci, resulting in altered penicillin-binding proteins.

^aLocations for manufacturers are as follows: ¹Indianapolis, IN; ²Sparks, MD;

³Marlborough, MA; ⁴Des Plaines, IL.; ⁵Sunnyvale, CA.

In addition to penicillin resistance, *N. gonorrhoeae* exhibits plasmid-mediated resistance and **chromosome-mediated resistance to tetracycline, spectinomycin, and the fluoroquinolones (e.g., ciprofloxacin)**. Spectinomycin resistance, first reported in the United States in 1981, is caused by a chromosomal mutation resulting in high-level resistance to the antimicrobial agent.

Because of concerns over the development of antimicrobial resistance by *N. gonorrhoeae*, the CDC developed the Gonococcal Isolate Surveillance Project (GISP) in 1986. This sentinel surveillance system monitors gonococcal antimicrobial susceptibility to provide treatment recommendations and to recognize treatment failures before they become a public health problem.

During the 1990s and 2000s, fluoroquinolones were recommended for treatment of gonorrhea because they were safe, cost-effective, and available in oral forms. Fluoroquinolone resistance was recognized by GISP monitoring, and by 2007, the CDC no longer recommended the use of fluoroquinolones for gonorrhea. Cephalosporins are currently the only antimicrobials remaining that are recommended for treatment; however, isolates with high-level cefixime and ceftriaxone minimal inhibitory concentrations have been identified.

Treatment

The 2020 Treatment Guidelines for Gonococcal Infection recommend a single 500mg intramuscular dose of ceftriaxone for uncomplicated gonorrhea. If chlamydial infection cannot be excluded, oral doxycycline (100mg twice daily for 7 days) should also be administered for co-infection with *C. trachomatis*.

Monitoring for the emergence of ceftriaxone resistance is imperative to ensure continued efficacy of the recommended treatment protocol. Surveillance and the reporting of treatment failures by health care providers are essential to ensuring therapeutic success.

Case check 17.2

The organism causing the infection in the Case in Point is *N. gonorrhoeae*. Direct Gram stain of the wrist aspirate revealed the presence of this bacterium. *N. meningitidis* could also result in this clinical picture; therefore laboratory testing is imperative. Culture of the fluid provided a clue to the identity when growth occurred on CHOC agar with no growth on SBA. *N. gonorrhoeae* is one of the few pathogens (*Haemophilus influenzae* is another) that does not usually grow on SBA. Presumptive testing included Gram stain of the colonies and an oxidase test. Definitive testing with a commercial coagglutination test kit was performed. The laboratory tested for β -lactamase with the Cefinase test. Some laboratories continue to perform β -lactamase testing on gonococcal isolates, although this is no longer necessary because penicillin has not been considered a therapeutic option for several years.

Neisseria meningitidis

Similar to *N. gonorrhoeae*, *N. meningitidis* is also found only in humans. However, *N. meningitidis* can be found as a commensal as well as an invasive pathogen. It is an important etiologic agent of endemic and epidemic meningitis and

meningococcemia and rarely pneumonia, purulent arthritis, or endophthalmitis. *N. meningitidis* has also been recovered from urogenital and rectal sites as a result of oral-genital contact. Meningococcal carriage, usually involving non-encapsulated strains, may cause an increase in protective antibodies against the pathogenic strains.

Epidemiology

N. meningitidis can be found on the mucosal surfaces of the nasopharynx and oropharynx in 30% of the population. The organism is transmitted by close contact with respiratory droplet secretions from a carrier to a new host. Only a few newly colonized hosts develop meningococcal disease, with the highest incidence being found in infants and adolescents.

Increased risk of invasive disease occurs in individuals with asplenia or individuals with complement deficiencies. Smoking, exposure to smoke, or concurrent upper respiratory tract viral infection can also lead to serious disease. Crowded living conditions can facilitate the spread of meningococcus because individuals from different areas can be colonized by different strains. Military recruits and resident college students have an increased risk of exposure because of living in close quarters. In one study of university students, nasopharyngeal carriage increased significantly during the first few weeks of the academic year.

Of the 12 meningococcal encapsulated serogroups, A, B, C, Y, and W-135 account for most cases of disease in the world. Invasive meningococcal disease is uncommon in developed nations. Serogroups B, C, and Y are most common in the United States and Europe. Meningococcal disease in the United States has been declining since the 1990s. In 2019, 375 cases were reported to the CDC—an incidence rate of 0.11/100,000 population. An area of sub-Saharan Africa referred to as the “meningitis belt” frequently experiences epidemics during the hot and dry season. The infection rates are approximately 1000 per 100,000 in this area with a population of 300 million, with serogroup A historically accounting for most of the cases. In 2010, a mass serogroup A vaccine campaign was started in the meningitis belt countries, and epidemics caused by serogroup A have been eliminated. Recent outbreaks in this area have been primarily caused by serogroups C and W.

Clinical infections

After exposure to meningococcus, the incubation period ranges from 1 to 10 days. The bacteria adhere to the nasopharyngeal mucosa, leading to colonization. In most individuals, colonization of the mucosa results in a subclinical infection or mild symptoms. In a few hosts, the bacteria gain access to the bloodstream and potentially the central nervous system, resulting in meningitis, sepsis, or both.

When *N. meningitidis* enters the bloodstream, two main diseases can occur: fulminant meningococcemia or meningitis. Meningococcemia, or sepsis, may occur with or without meningitis and carries a 25% mortality rate, even if treated. Purpura (hemorrhaging of blood into skin and mucous membranes, producing bruises) with petechial skin rash (pinpoint red spots caused by hemorrhage) (Fig. 17.8A), tachycardia, and hypotension can develop during bacteremia, and thrombosis is common. In some cases, the disease becomes

Fig. 17.8 A, Petechial skin rash associated with meningococcemia in an infant. B, Hemorrhage (dark red areas) in the adrenal glands in Waterhouse-Friderichsen syndrome.

fulminant and spreads rapidly, causing disseminated intravascular coagulation, septic shock, or hemorrhage in the adrenal glands (Waterhouse-Friderichsen syndrome) (see Fig. 17.8B). Death may occur in 12 to 48 hours from onset. Individuals with a deficiency in complement components C5 to C8 are at increased risk of meningococcemia. Meningitis is characterized by an abrupt onset of frontal headache, stiff neck (nuchal rigidity), confusion, and photophobia. The fatality rate is 10% to 15%; an additional 10% to 20% have serious sequelae, such as neurologic complications or seizures. Other complications include arthritis, pericarditis, and pneumonia. Meningococcal pneumonia is usually caused by serogroup Y and affects older adults with underlying pulmonary problems. On rare occasions, *N. meningitidis* can cause conjunctivitis and urethritis.

Laboratory diagnosis

Specimen collection and transport

Specimens for the recovery of *N. meningitidis* may come from a wide variety of sterile and nonsterile sites. These include cerebrospinal fluid (CSF), blood, nasopharyngeal swabs and aspirates, joint fluids, and, less commonly, sputum and material from urogenital sites. Collection and transport should be performed as specified by the laboratory for the various specimen types. Because *N. meningitidis* is inhibited by SPS, when commercial blood culture systems are used, information from the manufacturer should be consulted to determine whether *N. meningitidis* can be recovered.

Direct microscopic examination

On Gram-stained smears from specimens, such as CSF, meningococci appear as intracellular and extracellular gram-negative diplococci (Fig. 17.9). The highest yield of positive results of CSF Gram stain is obtained when specimens are concentrated. At least 1 mL of CSF should be centrifuged at $\times 1000g$ for 10 minutes and the sediment used for slide preparation and culture. The use of a cytocentrifuge is recommended and increases the sensitivity for detection by concentrating small numbers of organisms 100-fold. In a patient who has disseminated meningococcemia with petechiae from hemorrhage of surface blood vessels, impression Gram stain is often positive for gram-negative diplococci.

Fig. 17.9 Direct Gram-stained smear of cerebrospinal fluid illustrating intracellular and extracellular gram-negative diplococci (arrows) of *Neisseria meningitidis* (×1000).

Fig. 17.10 Growth of *Neisseria meningitidis* after 48 hours on chocolate (CHOC) agar (left) and sheep blood agar (SBA) (right). Of the *Neisseria* pathogens, only the meningococcus grows on SBA and CHOC agar.

Culture and incubation

Specimens for isolation of *N. meningitidis* should be cultured on SBA and CHOC agar. Specimens from mucosal surfaces that contain normal microbiota should also be inoculated to a selective medium, as described earlier for the culture of *N. gonorrhoeae*. Cultures should be incubated in the same atmospheric conditions described for *N. gonorrhoeae* and examined daily for 72 hours.

Identification

Presumptive identification is based on colony morphology, microscopic morphology, and the oxidase test. Colonies of meningococci usually grow within 18 to 24 hours and, in contrast with *N. gonorrhoeae*, grow well on SBA. The colonies are medium size, gray, and convex, and encapsulated strains are mucoid. The blood agar underneath the colonies tends to have a green tinge. *N. meningitidis* also grows on the selective agars, producing colorless to gray, convex, smooth colonies (Fig. 17.10).

N. meningitidis appears as gram-negative diplococci with adjacent sides flattened. Testing must be performed to confirm that the isolate is oxidase positive. Details of this test are described under *N. gonorrhoeae*. Definitive identification of *N. meningitidis* can be made with the use of carbohydrate methods, chromogenic enzyme tests, or multitest assays. In the carbohydrate utilization methods, *N. meningitidis* uses glucose and maltose. *N. lactamica*, generally a nonpathogenic species that may mimic *N. meningitidis*, can also grow on selective media. The lactose-positive characteristic of *N. lactamica* may be delayed or absent. A rapid *o*-nitrophenyl- β -D-galactopyranoside (ONPG) test, which detects lactose utilization, is usually positive in 30 minutes for *N. lactamica*. See Chapter 9 for a description of the ONPG test.

Although rare, *N. meningitidis*, as well as *N. gonorrhoeae*, may fail to acidify carbohydrate-containing media. Maltose-negative strains of *N. meningitidis* could be misidentified as *N. gonorrhoeae*, especially if recovered from the genital tract or other unusual sites. Maltose-negative strains may lack the maltose phosphorylase pathway; this occurs mainly in serogroup B but also rarely in groups C and Y. To avoid misidentification of maltose-negative strains, enzyme tests and multitest methods can be utilized. One useful test included in some identification systems is γ -glutamyl aminopeptidase, which is usually positive for *N. meningitidis* and negative for *N. gonorrhoeae*, *N. lactamica*, and *M. catarrhalis*.

If testing identifies the isolate as *N. meningitidis*, serologic testing should be performed to determine the serogroup. Isolates can be sent to a reference or public health laboratory for serogrouping. Additional methods using molecular techniques and MALDI-TOF mass spectrometry are also available.

Laboratory-acquired disease

In 2000, two cases of fatal laboratory-acquired meningococcal disease were reported to the CDC. Both clinical microbiologists had examined plates, performed Gram stain, subcultured, or performed slide agglutination serogrouping on patient isolates on the open bench. Isolates recovered from the laboratory scientists were identical to patient organisms. A retrospective survey identified 16 probable laboratory-acquired meningococcal infections worldwide from 1996 to 2001. Because exposure to *N. meningitidis* aerosols increases risk of infection, the CDC recommends the use of a biosafety level 2 cabinet for manipulation of suspected isolates of *N. meningitidis* from sterile sites.

Treatment

Empiric therapy for suspected meningococcal disease consists of an extended-spectrum cephalosporin (cefotaxime or ceftriaxone). Upon confirmation of the microbiologic diagnosis, definitive treatment with penicillin G, ampicillin, or an extended-spectrum cephalosporin is recommended. Routine susceptibility of *N. meningitidis* was not previously recommended; however, recent reports of β -lactamase-producing *N. meningitidis* serogroup Y cases in the United States have prompted a recommendation that susceptibility to penicillin be determined before administering.

Close contacts of patients with invasive meningococcal disease are at increased risk of contracting this infection. Chemoprophylaxis with rifampin, ceftriaxone, or ciprofloxacin is recommended for contacts. **Azithromycin is not recommended as a first-line chemoprophylactic agent, but it can be used in areas where ciprofloxacin resistance is a problem. Chemoprophylaxis is not recommended for asymptomatic carriers.**

Vaccine

Three quadrivalent polysaccharide–protein conjugated vaccines with antigens to serogroups A, C, Y, and W-135 are available in the United States. These vaccines are licensed for use in individuals 2 to 55 years of age. The Advisory Committee on Immunization Practices recommends routine vaccination of individuals at 11 to 12 years of age, with a booster dose administered at 16 years of age. If not previously vaccinated, individuals entering high school and college freshmen living in dormitories should receive this vaccine. Meningococcal vaccine is also recommended for military recruits, patients with asplenia who are older than 2 years of age, and laboratory scientists who work with *N. meningitidis*. Individuals who receive their first dose at 16 years of age or older do not need a booster dose unless they are at a high risk of invasive meningococcal disease.

In 2014 and 2015, two vaccines against *N. meningitidis* serogroup B were approved. The capsular antigen B is weakly antigenic, and because of its similarity to human glycoproteins, it can cause hypersensitivity reactions as a result of molecular mimicry. The vaccines are conjugated vaccines of proteins from other bacteria bound to *N. meningitidis* group B outer membrane proteins. Vaccination is recommended for young adults 16 to 23 years of age and will provide short-term protection against 91% of meningococcal B strains in the United States. This vaccine is administered as a two- or three-dose series and is recommended for individuals at increased risk of meningococcal group B disease.

Moraxella catarrhalis

Clinical infections

M. catarrhalis, a commensal of the upper respiratory tract isolated only from humans, is an opportunistic pathogen. It is recognized as a cause of upper respiratory tract infection in otherwise healthy children and in older adults. This organism has been reported as the third most common cause of acute otitis media and sinusitis in children, following *Streptococcus pneumoniae* and *Haemophilus influenzae* (Fig. 17.11A). The exact pathogenesis of otitis media is not clear, but colonization and persistence in the nasopharynx is accepted to be the initiating step. The mechanism of transition from colonization to infection is not understood, but it is accepted that a viral upper respiratory infection causes changes in the host that leads to the onset of acute otitis media. Recent studies indicate that biofilms and polymicrobial infections are a significant factor in recurrent and chronic infections that are difficult to eradicate. *M. catarrhalis* is more often found in polymicrobial otitis media infections than from a single-species infection.

Fig. 17.11 **A**, Direct Gram-stained smear of an otitis media specimen illustrating intracellular, gram-negative diplococci ($\times 1000$). The organism was identified biochemically as *M. catarrhalis* from cultures. **B**, Growth of *Moraxella catarrhalis* after 48 hours, illustrating the “wagon-wheel” appearance on chocolate agar.

M. catarrhalis can also cause lower respiratory tract infections including bronchitis and pneumonia, especially in adults with chronic obstructive pulmonary disease. Other predisposing factors include advanced age, immunodeficiency, neutropenia, and chronic debilitating diseases. Additional rare infections include life-threatening systemic diseases, such as endocarditis, meningitis, and bacterial tracheitis. Severe infections are seen in immunocompromised hosts; hospital outbreaks of *M. catarrhalis* respiratory infections have occurred. The presence of intracellular, gram-negative diplococci in these specimens may alert the microbiologist to possible infection with *M. catarrhalis*. Most isolates produce β -lactamase, making them resistant to ampicillin and amoxicillin. Antimicrobial agents used include amoxicillin-clavulanic acid, extended-spectrum cephalosporins, azithromycin, and trimethoprim-sulfamethoxazole.

Laboratory diagnosis

Specimen collection and identification

Typical specimens for *M. catarrhalis* can be collected from middle ear effusion, nasopharynx, sinus aspirates, sputum, or bronchial aspirates. The organism grows on SBA and CHOC

agar, producing smooth, opaque, gray-to-white colonies. The term *hockey puck* has been used to describe the colony because it remains intact when pushed across the plate with a loop. Older colonies may give a “wagon-wheel” appearance (see Fig. 17.11B). In contrast with *Neisseria* spp. that have an optimal growth temperature of 35° to 37° C, most strains of *M. catarrhalis* can tolerate lower temperatures and grow well at 28°C. *M. catarrhalis* is usually inhibited on gonococcal selective agars by colistin, but some strains resistant to this antimicrobial may grow. Similar to *Neisseria* spp., *M. catarrhalis* is oxidase and catalase positive. The organism is asaccharolytic, and it may be differentiated from *Neisseria* spp. by positive DNase and butyrate esterase reactions. Tributyrin is used as the substrate to detect butyrate esterase activity. MALDI-TOF mass spectrometry provides rapid and accurate identification.

Commensal *Neisseria* species

Other *Neisseria* spp. exist as normal inhabitants of the upper respiratory tract. Referred to as *commensals*, *saprophytes*, or *nonpathogens*, these species are occasionally isolated from the genital tract. The commensal *Neisseria* spp. rarely cause disease, but they have sporadically been implicated in meningitis, endocarditis, prosthetic valve infections, bacteremia, pneumonia, empyema, bacteriuria, osteomyelitis, and ocular infections (Table 17.6). Many rapid tests for the identification

Table 17.6 Infections reported to be caused by <i>Neisseria</i> species other than <i>N. gonorrhoeae</i> and <i>N. meningitidis</i>	
Infection	<i>Neisseria</i> species
Meningitis	<i>N. lactamica</i>
	<i>N. sicca</i>

Bacteriuria	<i>N. subflava</i>
Osteomyelitis	<i>N. sicca</i>
Ocular infection	<i>N. cinerea</i>
Dog bite	<i>N. mucosa</i>
	<i>N. weaveri</i>

of *N. gonorrhoeae* test for a limited number of characteristics that may be shared by one or more nonpathogenic *Neisseria* spp. One must keep in mind that the incidence of infections caused by the commensal *Neisseria* spp. is extremely low and that the main reason for the clinical microbiologist to be familiar with these organisms is to accurately separate them from the pathogenic species.

Identification

Table 17.7 lists the colony morphology and primary isolation sites of the *Neisseria* spp. and related organisms. Table 17.8 lists the traditional and additional tests used to identify the *Neisseria* spp. and some similar genera. These organisms are divided into three groups as follows:

- Group 1: Traditional pathogens
 - Group 2: Commensal *Neisseria* spp. that can grow on selective media
 - Group 3: Commensal *Neisseria* spp. that do not usually grow on selective media
- Groups 2 and 3 are divided further on the basis of their activities toward carbohydrates.

In the clinical laboratory, when isolated from respiratory specimens, commensal *Neisseria* spp. are usually identified only with Gram stain and gross colony morphology and are called *Neisseria* spp. or *usual oral biota*. Further identification by biochemical tests is not done. When they are isolated from selective agar or sterile body sites, differentiation from the pathogenic *Neisseria* may be required. Common laboratory tests and observations do not always adequately differentiate all of the commensal species from one another or from the pathogens. In addition, insufficient test parameters and equivocal carbohydrate reactions have led to confusion between the pathogenic and commensal *Neisseria* spp. Additional tests used to help further differentiate these organisms include growth on nutrient agar at 35°C, growth on SBA or CHOC agar at 22°C, and the reduction of nitrate and nitrite.

Neisseria cinerea

N. cinerea has received considerable attention in recent years because of its misidentification as *N. gonorrhoeae* in some commercial identification systems. Although *N. cinerea* is glucose negative in CTA sugars, the glucose was interpreted as positive in some commercial kits, making it biochemically identical to *N. gonorrhoeae*. The colony morphology of *N. cinerea* is also similar to the T3 colonies of *N. gonorrhoeae* on CHOC agar. Some strains of *N. cinerea* will grow on gonococcal selective medium. *N. cinerea* will grow well on SBA (Fig. 17.12), whereas *N. gonorrhoeae* usually does not.

Colistin susceptibility is a helpful test in differentiating *N. cinerea* from *N. gonorrhoeae*. A suspension of the organism is swabbed onto an SBA or CHOC agar plate, a 10-μg colistin disk is applied to the inoculum, and the plate is incubated in CO₂ for 18 to 24 hours. *N. cinerea* is susceptible (≥10 mm zone of inhibition) to colistin, whereas *N. gonorrhoeae* is resistant. Useful tests for differentiation of *N. cinerea* from *M. catarrhalis* are reduction of nitrate and negative DNase reaction. Useful observation for differentiation from *Neisseria flavescens* is lack of yellow pigment production.

Table 17.7 Colony morphology and primary isolation sites of *Neisseria* and related organisms

Organism	Colony morphology ^a	Primary isolation sites
<i>N. gonorrhoeae</i>	Small (0.5–1 mm), grayish white, translucent, raised with entire edge Usually easily emulsified Smaller than <i>N. meningitidis</i> Up to five different colony morphologies from primary culture	Male: urethra Female: endocervix Laboratory should be notified to look for this organism from other sites so appropriate media can be used
<i>N. meningitidis</i>	1–2 mm, bluish gray or tan (serogroup 6 may be yellowish) Serogroups A and C may be mucoid, translucent, and convex with smooth glistening surface; may be greenish cast in agar around colonies Usually easily emulsified	Nasopharynx and oropharynx (carriers) Spinal fluid: meningitis Blood: meningococcemia Lower respiratory tract: meningococcal pneumonia
<i>N. polysaccharea</i>	Small, gray (sometimes yellowish), translucent, raised Resembles <i>N. gonorrhoeae</i> colony	Nasopharynx of infants and children
<i>N. lactamica</i>	Small, grayish white (often with a yellow ring), translucent, slightly butyrous Resembles <i>N. meningitidis</i> but smaller	Nasopharynx of infants and children Rarely found in adults
<i>N. cinerea</i>	Small (1–1.5 mm), grayish white, translucent, raised with entire edge and slightly granular Resembles <i>N. gonorrhoeae</i>	Nasopharynx
<i>N. mucosa</i>	Large (up to 4 mm), grayish to buff yellow, translucent and mucoid, smooth surface, entire edge Viscous (sticky) consistency	Nasopharynx
<i>N. sicca</i>	Large (up to 3 mm), grayish white, opaque, deeply wrinkled, dry, irregular (breadcrumb-like) colony Firmly adherent, difficult to impossible to emulsify	Nasopharynx, saliva, sputum
<i>N. subflava biovars</i>	0.5–2 mm, pale greenish yellow to yellow, smooth surface with entire edge Often adherent	Nasopharynx
<i>N. flavescens</i>	Colonies similar to <i>N. meningitidis</i> but with golden yellow pigment	Pharynx (not often isolated from clinical specimens)
<i>N. elongate</i>	Large (up to 3 mm), grayish white with yellowish tinge, low convex to almost flat Corroding of agar may occur Claylike colony, difficult to emulsify	Nasopharynx
<i>N. weaver</i>	Small, semi-opaque with smooth appearance	Wounds from dog bites
<i>N. bacilliformis</i>	Small, smooth, glistening, light gray to buff	Upper respiratory tract
<i>Kingella denitrificans</i>	Small (1–2 mm), gray, semi-transparent, convex, may pit the agar Colony morphology of organisms that do not pit the agar similar to <i>N. gonorrhoeae</i>	Upper respiratory tract
<i>Moraxella catarrhalis</i>	3–5 mm, grayish white, opaque 48-hour colony may have elevated center and thinner, wavelike periphery ("wagon wheel") Often granular, difficult to emulsify Colony can be swept across plate intact ("hockey puck")	Upper respiratory tract

^aOn chocolate agar at 24 to 48 hours.

Fig. 17.13 Culture of *Neisseria lactamica* after 48 hours on sheep blood agar (left) and chocolate agar (right). This organism resembles *Neisseria meningitidis*.

Neisseria flavescens

N. flavescens (*flavescens* means “yellow”) is a yellow-pigmented *Neisseria* species that is asaccharolytic. It can be differentiated from *N. cinerea* by its ability to grow on SBA or CHOC agar at 22° C and its yellow colonies.

Neisseria lactamica

N. lactamica is commonly found in the nasopharynx of infants and children and, similar to *Neisseria polysaccharea*, is commonly encountered in meningococcal carrier surveys. The carriage rate of this species in children appears to peak at about 2 years of age and then steadily declines. It is rarely isolated from adults. It is the only *Neisseria* species that uses lactose—hence its species designation *lactamica*.

N. lactamica can be misidentified as *N. meningitidis* because of its similar colony morphology (*N. lactamica* is slightly smaller) (Fig. 17.13) and its ability to grow on selective media. Although *N. lactamica* uses glucose, maltose, and lactose, it can exhibit delayed lactose utilization and be confused with *N. meningitidis*. The definitive test for differentiation from *N. meningitidis* and all other *Neisseria* spp. is lactose utilization or positive ONPG reaction.

Neisseria mucosa

Colonies of *N. mucosa* are large, often adherent to the agar, and very mucoid, giving the species its name. *N. mucosa* is usually isolated as a nonpathogen from the nasopharynx of children or young adults. This organism has been documented to cause pneumonia in children. In addition, it has been associated with bacteremia and endocarditis in patients with neutropenia. It has the same carbohydrate pattern as *N. sicca* and *N. subflava* biovar *perflava*, but it differs from these species in its ability to reduce nitrite to nitrogen gas, its colony morphology, and its lack of pigment production.

Neisseria sicca

The colonies of *N. sicca* are usually dry, wrinkled, adherent, and breadcrumb-like (Fig. 17.14). The Latin word *sicca* means “dry.” *N. sicca* and *N. subflava* biovar *perflava* are usually the

Fig. 17.14 Dry, wrinkled, breadcrumb-like colony morphology of *Neisseria sicca* on sheep blood agar (48-hour culture).

two most common *Neisseria* spp. found in the respiratory tract of adults. It has been reported to cause endocarditis.

Neisseria subflava

The species name for *N. subflava* means “less yellow” (Fig. 17.15). The organism is considered part of the upper respiratory microbiota. It consists of three biovars that differ from one another by their patterns of carbohydrate utilization. Although it is considered a nonpathogen, it has been reported to cause serious infections, such as bacteremia, meningitis, and septicemia. Its clinical description may resemble *N. meningitidis* infection, including septic shock, petechial hemorrhage, and purpura. It has reduced sensitivity to penicillin, cefixime, and ciprofloxacin.

Neisseria elongata

Neisseria elongata, *N. weaveri*, and *N. bacilliformis* are unique among the members of the genus *Neisseria* in that they are rod shaped. *N. elongata* contains three subspecies: *elongata*, *glycolytica*, and *nitroreducens*. The catalase test for all subspecies is

Fig. 17.15 Yellow pigmentation of *Neisseria subflava* on sheep blood agar (48-hour culture).

negative or weakly positive compared with other *Neisseria* spp. All three subspecies are commensals in the upper respiratory tract and are considered opportunistic pathogens. Several cases linking *N. elongata* to endocarditis have been reported.

Neisseria weaveri

N. weaveri is normal oral microbiota in dogs and can be found in humans in infections following dog bites. It is catalase positive and does not produce acid from any of the carbohydrates traditionally used to identify *Neisseria* spp. *N. weaveri* is a gram-negative rod that does not reduce nitrate but does reduce nitrite to gas. It is also weakly phenylalanine deaminase positive. Rare cases of septicemia in immunocompromised patients have been reported. This organism is usually sensitive to penicillin.

POINTS TO REMEMBER

- Most *Neisseria* spp. are gram-negative diplococci that occur in pairs, with adjacent sides flattened.
- Species of the genus *Neisseria* are oxidase-positive, aerobic organisms that grow best in increased CO₂ and humidity.
- *N. gonorrhoeae* and *N. meningitidis* are the primary human pathogens of the genus.
- All other *Neisseria* species are considered opportunistic pathogens and must be differentiated from *N. gonorrhoeae* and *N. meningitidis*.
- Pathogenic species are fastidious organisms requiring enriched and selective media for optimal recovery.
- Growth of the primary human pathogens on selective media, such as modified Thayer-Martin (MTM) or New York city agars, is not considered confirmatory. Gram stain of the colony, oxidase, and additional laboratory tests must be performed to confirm identification.
- *M. catarrhalis* is a commensal of the upper respiratory tract and is associated with opportunistic infections, including otitis media, sinusitis, and lower respiratory tract infections.
- *M. catarrhalis* is asaccharolytic, and it is differentiated from *Neisseria* spp. by being tributyrin hydrolysis positive or DNase positive.
- The incidence of infections caused by commensal *Neisseria* spp. is very low. They are not usually identified unless found in a specimen from a normally sterile site and are rarely associated with septicemia and endocarditis.

LEARNING ASSESSMENT QUESTIONS

1. Which characteristics do most *Neisseria* species have?
 - a. Oxidase-positive, gram-positive diplococci
 - b. Oxidase-positive, gram-negative diplococci
 - c. Oxidase-negative, gram-negative diplococci
 - d. Oxidase-negative, gram-positive diplococci
2. Which virulence factor of the pathogenic *Neisseria* spp. is responsible for the initial attachment of the organism to host tissues?
 - a. Pili
 - b. Endotoxin
 - c. Cell membrane proteins
 - d. Peptidoglycan
3. Asymptomatic gonococcal infections in women may result in which condition?
 - a. Pelvic inflammatory disease
 - b. Ectopic pregnancy
 - c. Fitz-Hugh–Curtis syndrome
 - d. All of the above
4. Which is the optimal specimen to collect for the diagnosis of gonorrhea by culture in male patients?
 - a. Pharyngeal swab
 - b. Rectal swab
 - c. Urethral swab
 - d. Urine
5. Which of the following is (are) the reason(s) direct Gram stain is performed for the diagnosis of gonorrhea?
 - a. Is appropriate on vaginal specimens
 - b. Can accurately detect urethritis in males
 - c. Can accurately diagnose gonococcal pharyngitis
 - d. All of the above
6. Which selective medium allows the isolation of *N. gonorrhoeae* and *N. meningitidis*?
 - a. Phenylethyl alcohol blood agar
 - b. Chocolate (CHOC) agar
 - c. Columbia nalidixic acid
 - d. Modified Thayer-Martin (MTM) agar
7. Which test can be used for definitive identification of both *N. gonorrhoeae* and *N. meningitidis*?
 - a. Gram stain
 - b. Catalase
 - c. Oxidase
 - d. Rapid carbohydrate utilization
8. What is the advantage of nucleic acid amplification tests for diagnosing gonorrhea?
 - a. Are approved for use in testing in boys in cases of sexual abuse
 - b. Detect viable organisms in the specimen
 - c. Are sensitive and do not require invasive specimens
 - d. Require strict transport conditions

9. What are the current recommendations for treatment of genital gonorrhea?
10. Which opportunistic pathogen is asaccharolytic, tributyrin hydrolysis positive, and DNase positive?
 - a. *Kingella denitrificans*
 - b. *Neisseria mucosa*
 - c. *Neisseria lactamica*
 - d. *Moraxella catarrhalis*
11. Entrance of *N. meningitidis* into the bloodstream may lead to which condition?
 - a. Meningococcemia
 - b. Meningitis
 - c. Waterhouse-Friderichsen syndrome
 - d. All of the above
12. Which test can accurately differentiate *N. lactamica* from *N. meningitidis*?
 - a. ONPG
 - b. Catalase
 - c. Acid from maltose
 - d. Acid from sucrose
13. Which organism is an opportunistic pathogen associated with otitis media and sinusitis in children?
 - a. *Moraxella catarrhalis*
 - b. *Neisseria lactamica*
 - c. *Neisseria meningitidis*
 - d. *Neisseria sicca*
14. Describe the colony morphology of *M. catarrhalis*, and explain how it is identified in the laboratory.
15. Erythromycin eye drops are placed into the eyes of newborns to prevent infections caused by which organism?
 - a. *Neisseria meningitidis*
 - b. *Neisseria gonorrhoeae*
 - c. *Neisseria cinerea*
 - d. *Moraxella catarrhalis*

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Distinguish each bacterial species discussed in this chapter by colony and microscopic morphology, habitat, nutritional requirements, and key identifying characteristics.
2. Compare the growth of the *Haemophilus* spp. colonies when performing tests for determination of X factor and V factor requirements.
3. Predict which antimicrobial agents to use in treating infections described in this chapter based on β -lactamase results.
4. Compare the pathogenesis, including modes of transmission, of each organism discussed.
5. Explain the clinical significance of the organisms discussed when isolated in the clinical laboratory.
6. Recommend the appropriate specimens for the recovery of these organisms.
7. Determine the appropriate culture media required for isolation of each organism.
8. Justify the use of nonculture laboratory methods used to detect these organisms.
9. Describe the genera and species of the organisms included in the acronym HACEK and the major diseases they cause.
10. Identify the most common animal reservoir for members of the genera *Pasteurella*, *Brucella*, and *Francisella*.
11. Associate the risk factors for acquiring legionellosis.
12. Compare Legionnaires' disease with Pontiac fever.
13. Discuss rapid assays useful in the detection of *Legionella* spp.
14. Describe the composition and efficacy of the vaccine for pertussis.

15. Develop an algorithm for the diagnosis of pertussis from specimen collection to identification of the causative agent.
16. Discuss the serologic response to *Bordetella pertussis* infection.

KEY TERMS

Adenylate cyclase toxin	HACEK
δ -Aminolevulinic acid (ALA)	Legionnaires' disease
Atypical pneumonia	Nontypable <i>H. influenzae</i> (NTHi)
Bipolar staining	Paroxysmal phase
Bordet-Gengou potato infusion agar	Pertussis
Buboes	Pertussis toxin (PT)
Buffered charcoal yeast extract (BCYE)	Pontiac fever
Buffered charcoal yeast extract with 0.1% α -ketoglutaric acid (BCYE α)	Porphyria
Capnophilic	Regan-Lowe transport medium
Catarrhal phase	Satellitism
Chancroid	Select biological agent
Convalescent phase	Suppurative
Filamentous hemagglutinin (FHA)	Tracheal cytotoxin
Genital ulcer disease (GUD)	V factor (nicotinamide adenine dinucleotide [NAD])
	Whooping cough
	X factor (hemin or hematin)
	Zoonoses

Case in point

A 59-year-old female stroke victim was confined temporarily to a respite nursing home because her immediate family was on a short vacation. On admission, she complained of a slight respiratory ailment. She awoke 3 days later with a stiff neck and a severe headache. Because of a high fever and other signs and symptoms of meningitis, she was transported to a nearby hospital emergency department, where a lumbar puncture was performed. Her cerebrospinal fluid (CSF) was cloudy, with an elevated protein concentration and a decreased glucose concentration, and more than 420 white blood cells (WBCs)/mL were noted; 92% were polymorphonuclear cells. Direct Gram-stained smear revealed many WBCs and many small, gram-negative bacilli; some appeared coccobacillary with clear halos around them. Cultures of CSF and blood produced heavy bacterial growth on chocolate (CHOC) agar but not on sheep blood agar (SBA) or MacConkey (MAC) agar.

Issues to consider

After reading the patient's case history, consider:

- The factors that would have predisposed the patient to meningitis
- Whether a vaccine for the etiologic agent in question is available
- The primary causes of meningitis in patients in this age group
- The characteristics of the microscopic morphology and growth patterns on laboratory media that help provide a presumptive identification

This chapter describes miscellaneous, fastidious, pleomorphic (many shapes), small, gram-negative bacilli. Most of these organisms require special nutrients for isolation and identification. *Haemophilus* spp. are facultative anaerobes and obligate parasites that are primarily adapted to

the respiratory tract of humans and other animals. One major exception is *Haemophilus ducreyi*, which causes the sexually transmitted disease (STD) **chancroid**. The genera *Haemophilus*, *Actinobacillus*, *Pasteurella*, and *Aggregatibacter* belong to the family Pasteurellaceae. Pasteurellaceae are characteristically gram-negative, pleomorphic, coccoid-shaped to rod-shaped cells that are nonmotile and facultatively anaerobic. They form nitrites from nitrates and are oxidase and catalase positive. Specific species of the genera *Haemophilus*, *Aggregatibacter*, *Cardiobacterium*, *Eikenella*, and *Kingella* have been grouped together under the acronym **HACEK** (first letter of each genus). They reside in the human oral cavity and nasopharynx, and some species have an enhanced capacity to cause endocarditis.

Other fastidious, gram-negative bacilli, including *Capnocytophaga*, *Brucella*, *Francisella*, *Legionella*, and *Bordetella* are discussed in this chapter. At the present time, 14 species of *Capnocytophaga* have been identified, and six of them inhabit the human oral cavity. The remaining species are primarily normal inhabitants of the oral cavities of dogs and cats. Many members of the genera *Pasteurella*, *Brucella*, and *Francisella* cause zoonoses (animal diseases that are transmitted to humans from the primary animal host).

The respiratory pathogens *Legionella* and *Bordetella* are aerobic organisms. *Legionella* are aquatic microorganisms that can thrive in a variety of environments, whereas *Bordetella* exists in the respiratory tract of humans and animals either as commensals or pathogens.

Haemophilus

General characteristics

The genus *Haemophilus* consists of gram-negative, pleomorphic coccobacilli or rods that can vary microscopically from small coccobacilli in direct smears of clinical material to long filaments occasionally seen in stained smears of colony growth. They are nonmotile and facultatively anaerobic, ferment carbohydrates, are generally oxidase and catalase positive, reduce nitrates to nitrites, and are obligate parasites on the mucous membranes of humans and animals. There are approximately 13 species of *Haemophilus*. The eight species associated with humans are *H. influenzae*, *H. parainfluenzae*, *H. haemolyticus*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. pittmaniae*, *H. aegyptius*, and *H. ducreyi*. *H. segnis* was renamed *Aggregatibacter segnis*. Two other former members of the genus *Haemophilus*—*H. aphrophilus* and *H. paraphrophilus*—were also moved into the genus *Aggregatibacter* and combined into the single species *A. aphrophilus*. The *Aggregatibacter* spp. are also discussed in this chapter.

Most members of the genus *Haemophilus* are nonpathogenic or produce opportunistic infections. The emphasis of this section is on the major pathogenic species: *H. influenzae*, *H. aegyptius*, and *H. ducreyi*. *Haemophilus* is derived from the Greek word meaning “blood-lover.” As the name implies, *Haemophilus* organisms require preformed growth factors present in blood: **X factor** (hemin or hematin; X for “unknown”), **V factor** (nicotinamide adenine dinucleotide [NAD]; V for “vitamin”), or both. Traditionally, a small, gram-negative bacillus or coccobacillus is assigned to this

genus based on its requirements for one or both of the growth factors. *Haemophilus* spp. with the prefix *para* require only V factor for growth.

The production of hemolysis on 5% horse or rabbit blood agar is an important differential characteristic. Although certain species are also hemolytic on SBA, the organisms do not grow in pure culture on this medium. Both X and V factors are found within red blood cells (RBCs); however, only X factor is directly available. *Haemophilus* spp. that are V factor dependent do not grow on SBA because RBCs are still intact, and the sheep RBCs contain enzymes (NADases) that hydrolyze V factor. Clinical laboratories use chocolate (CHOC) agar for the recovery of *Haemophilus* spp. from clinical specimens. The lysing of the RBCs by heat in the preparation of CHOC agar releases both X factor and V factor and inactivates NADases. Supplemental nutrients are added.

A phenomenon that helps in the recognition of *Haemophilus* spp. that require V factor is **satellitism**. Satellitism occurs when an organism, such as *Staphylococcus aureus*, *Streptococcus pneumoniae*, or *Neisseria* spp., produces V factor as a by-product of metabolism. The *Haemophilus* isolate obtains X factor from the SBA and V factor from one of these organisms. On SBA plates, tiny colonies of *Haemophilus* may be seen growing around the V factor-producing organism. Fig. 18.1 illustrates *H. influenzae* satellitism around colonies of *S. aureus*. Except for *H. ducreyi*, all clinically significant *Haemophilus* spp. require V factor for growth and display this unusual growth pattern.

The indigenous microbiota of the healthy upper respiratory tract consists of many different genera and species of bacteria (see Chapters 2 and 32). Approximately 10% of this normal bacterial biota in adults consists of *Haemophilus* spp., with most of the organisms being *H. parainfluenzae* and, to a lesser extent, non-encapsulated *H. influenzae* that combined are carried by greater than 90% of healthy individuals. Colonization by *Haemophilus* spp. begins in infancy.

Fig. 18.1 *Haemophilus influenzae* satellitism around and between large, white, hemolytic staphylococci. The small, gray glistening colony is *H. influenzae* (arrow).

Haemophilus influenzae

Historic perspective

Influenza, commonly referred to as the *flu*, is a viral disease characterized by acute inflammation of the upper airways. Symptoms often progress to intense inflammation of the mucous membranes lining the nose (coryza), headache, bronchitis, and severe generalized muscle pain (myalgias). *H. influenzae* was erroneously named during the influenza pandemic that ravaged the world from 1889 to 1890. The basis for this assumption was the frequent isolation of this bacillus from the nasopharynx of patients with influenza and from postmortem lung cultures (viral isolation methods were unavailable). After viral culture techniques were developed, it became apparent that influenza was caused by a virus and that the actual role of *H. influenzae* was that of a secondary (opportunistic) invader.

Virulence factors

H. influenzae, the major pathogen within the genus, has a wide range of pathogenic potential. The following virulence factors play a role in the initiation of infection and the invasiveness of this organism:

- Capsule
- Immunoglobulin A (IgA) proteases
- Adherence by fimbriae and other structures
- Outer membrane proteins and lipopolysaccharide (LPS)

Capsule

Of all of the virulence factors, the capsule, if present, plays the most significant role. The serologic grouping of *H. influenzae* into six antigenically distinct types—a, b, c, d, e, and f—is based on differences in the capsular polysaccharide. Before widespread use of a vaccine, most invasive infections were caused by the encapsulated strain *H. influenzae* serotype b (Hib) and occurred primarily in young children. Serotype b strains are rarely seen now in children in countries using the vaccine; however, occasional serious invasive infections are seen in adults, especially in those older than 65 years of age. In unvaccinated children, type b is a leading cause of meningitis. In contrast with the other serotypes, the serotype b capsule is a unique polymer composed of ribose, ribitol, and phosphate (polyribitol phosphate). Evidence suggests that the antiphagocytic property and anticomplementary activity of the type b capsule are important factors in virulence and the pathogenesis of invasive disease. Not all strains of *H. influenzae* are encapsulated. These strains are commonly referred to as **nontypable *H. influenzae* (NTHi)**.

Immunoglobulin A proteases

Secretory IgA is present on human mucosal surfaces of the respiratory tract, areas for which *H. influenzae* has a predilection. IgA can bind to bacteria and block their attachment. *H. influenzae* is the only member of the genus that produces IgA protease. Because this enzyme can cleave secretory IgA, its production can contribute to the virulence of the organism.

Adherence mechanisms

The role of adherence mechanisms as virulence factors for *H. influenzae* is not well defined. Studies indicate that most NTHi strains are adherent to human epithelial cells, whereas most serotype b strains are not. The lack of this adherent capability in type b organisms may explain the tendency for type b strains to cause systemic infections. The presence of this adherent capability by NTHi strains may explain the tendency for these strains to cause more localized infections, such as acute conjunctivitis.

Outer membrane components

Although the role of outer membrane proteins and LPS is not well defined, antibodies directed against these antigens can play a significant role in human immunity. Each one of these components may be responsible for a specific activity, such as invasiveness, attachment, and antiphagocytic function. LPS has been shown to have a paralyzing effect on the sweeping motion of ciliated respiratory epithelium.

Clinical manifestations of Haemophilus influenzae infections

Two patterns of disease are attributed to *H. influenzae*. The first is invasive disease caused by encapsulated strains, in which bacteremia plays a significant role. Examples of invasive disease include septicemia, meningitis, arthritis, epiglottitis, tracheitis, and pneumonia. The second and the more common pattern of disease, as a result of Hib vaccination, is a more localized infection caused by the contiguous spread of NTHi strains, and it occurs within or in close proximity to the respiratory tract. Examples of localized infection include conjunctivitis, sinusitis, and otitis media with effusion (middle ear infections). *H. influenzae*, along with *Streptococcus pneumoniae*, is a common cause of middle ear infections in children. It has been demonstrated that the adenoids can serve as reservoirs in chronic middle ear infections and that the bacteria develop biofilms.

NTHi strains are also occasionally associated with invasive diseases, such as bronchitis and pneumonia, in older adult patients. High-risk factors include smoking, chronic obstructive pulmonary disease, and concurrent viral or bacterial infection. In contrast with encapsulated strains of *H. influenzae*, the NTHi strains can enter the central nervous system (CNS) by direct extension through infected sinuses, otitis media, and head trauma. Exceptions to the diseases caused by the encapsulated and NTHi strains do occur. NTHi strains can cause meningitis in adults, especially in immunocompromised or debilitated patients, and they can cause neonatal sepsis.

Before the advent of the Hib vaccine, the other serotypes rarely caused invasive disease in humans. Reports of infections have included pneumonia and bacteremia caused by serotypes a, d, and f in immunocompromised adults and neonatal sepsis caused by serotype c. Because of the widespread use of the Hib vaccine, hospital laboratories have reported a significant decrease in invasive disease among children, and diseases that do occur are generally caused by serotypes other than b. NTHi strains are currently responsible for most *H. influenzae* diseases in the United States. Data collected from the United States indicate that 70% of invasive *H. influenzae* infections were caused by NTHi. Serotype f (18%) accounted for the majority of invasive infections. Incidence is greatest among adults aged more than 65 years and children less than 1 year of age. The U.S. Centers

for Disease Control and Prevention (CDC) estimates that 6100 invasive case of *H. influenzae*, and 1015 deaths occur annually. In developing countries, where there is a lack of vaccination, serotype b is still a significant cause of bacterial pneumonia deaths and meningitis in children. *H. influenzae* remains a problem in older and debilitated people who have not been vaccinated. Table 18.1 summarizes infections caused by *H. influenzae*.

Case check 18.1

The older adult patient in the Case in Point had signs and symptoms of meningitis. The causative agent was a gram-negative bacillus that grew on CHOC agar but not on SBA or MAC agar. These characteristics strongly suggest *H. influenzae*. Determination of X factor and V factor requirement could confirm the diagnosis. Because of the routine use of a vaccine for *H. influenzae* type b, most invasive *H. influenzae* cases are caused by nontypable strains.

Meningitis

Before widespread use of the Hib vaccine, virtually all cases of meningitis caused by *H. influenzae* in children between 3 months and 6 years of age were caused by serotype b. Bloodstream invasion and bacteremic spread follow colonization, invasion, and replication of this organism in the respiratory mucous membranes. Headache, stiff neck, and other meningeal signs are usually preceded by mild respiratory disease.

Epiglottitis

The manifestations of epiglottitis include rapid onset, acute inflammation, and intense edema of the epiglottis that may cause complete airway obstruction, requiring an emergency tracheostomy. To avoid causing further possible damage, the area is not swabbed for culture but is treated empirically based on signs and symptoms. The peak incidence occurs in children between 2 and 4 years of age. Maintenance of a secure airway is the most important aspect of treatment.

Bacterial tracheitis

Similar to epiglottitis, bacterial tracheitis is a serious life-threatening disease in young children. It can arise after an acute, viral respiratory infection. Initially there is mild to moderate illness for approximately 2 to 7 days, but it progresses rapidly. Use of broad-spectrum antimicrobial agents during the early stages of the disease is imperative because thick secretions can occlude the trachea, so the disease must be differentiated from epiglottitis.

Table 18.1 Infections caused by *Haemophilus influenzae*

Encapsulated strains	Non-encapsulated strains
Septicemia	Otitis media with effusion
Septic arthritis	Conjunctivitis
Meningitis	Sinusitis
Osteomyelitis	Bacteremia
Cellulitis	Pneumonia ^a
Pericarditis	
Pneumonia	
Epiglottitis	

^aNontypable (non-encapsulated) strains cause lower respiratory tract infections primarily in older patients and individuals with underlying respiratory tract problems, including cystic fibrosis.

Infections associated with other *Haemophilus* species

Haemophilus aegyptius

H. aegyptius (Koch-Weeks bacillus) is genetically related to *H. influenzae*. Because of their similar identifying characteristics, it is difficult to differentiate *H. influenzae* from *H. aegyptius* and *H. influenzae* biogroup *aegyptius* in the clinical laboratory. *H. aegyptius* was observed by Koch in 1883 in Egyptians in conjunctivitis exudates—hence the species name. *H. aegyptius* is associated with an acute, contagious conjunctivitis, commonly referred to as *pink eye*.

Haemophilus influenzae biogroup *aegyptius*

H. influenzae biogroup *aegyptius* and *H. aegyptius* can cause conjunctivitis, primarily in pediatric populations. Despite being non-encapsulated, a clone of *H. influenzae* biogroup *aegyptius* first caused a severe systemic disease known as *Brazilian purpuric fever* (BPF) in Brazil in 1984. Currently, small outbreaks occasionally occur, primarily in South America. BPF is characterized by recurrent or concurrent conjunctivitis, followed by a sudden onset of high fever, petechial/purpurial rash, septicemia, shock, and vascular collapse. The mortality rate for BPF may reach 70% within 48 hours after onset.

Haemophilus ducreyi

H. ducreyi, a strictly human pathogen, is the causative agent of chancroid, a highly communicable sexually transmitted **genital ulcer disease (GUD)**. It infects the mucosal epithelium, genital and nongenital skin, and regional lymph nodes. Chancroid is commonly referred to as *soft chancre*, in contrast with the *hard chancre* of syphilis. Because chancroid facilitates the transmission of other STDs, all patients who have GUD should also be tested for human immunodeficiency virus (HIV), syphilis, and herpesvirus.

In contrast with other *Haemophilus* spp., this organism is not part of the normal microbiota. After an incubation period of approximately 4 to 14 days, a nonindurated, painful lesion with an irregular edge develops, generally on the genitalia or perianal areas. The most common sites of infection are on the penis or the labia or within the vagina. **Suppurative** (pus-forming), enlarged, draining, inguinal lymph nodes (**buboes**) are common in most infected patients (Fig. 18.2). Men have symptoms related to the inguinal tenderness and genital lesions, whereas most women are asymptomatic. Although less than 15 cases of chancroid are reported in the United States annually, as with *Neisseria gonorrhoeae* and *Chlamydia trachomatis*, cases are probably underreported. *H. ducreyi* is an important cause of GUD in Latin America, Africa, and Asia.

Miscellaneous species

H. parainfluenzae and the other species found in the oral cavity have a very low incidence of pathogenicity. *H. parainfluenzae* probably causes a few cases of otitis media and acute sinusitis and, although rare, has been implicated in cases of endocarditis. *H. parainfluenzae*-related endocarditis is a disease of insidious onset (i.e., a progressing disease without marked

Fig. 18.2 Lesions of chancroid on the penis, showing a draining bubo (arrow) in the adjacent groin area. Chancroid is caused by *Haemophilus ducreyi*.

symptoms before becoming apparent); first symptoms appear approximately 1 month after routine dental procedures. The mitral valve is the primary site of infection. In the absence of other pathogens, *H. parahaemolyticus* may be a cause of some cases of pharyngitis.

Laboratory diagnosis

Specimen processing and isolation

Haemophilus spp. have been associated with many diseases in humans. Almost any specimen submitted for routine bacteriologic examination may harbor these organisms. Common sources include blood, CSF, middle ear exudate, joint fluids, upper and lower respiratory tract specimens, swabs from conjunctivae, vaginal swabs, and abscess drainage. For culture of the lower respiratory tract, bronchial washing is recommended. Except in the case of patients with cystic fibrosis, nasal and nasopharyngeal swab specimens have no clinical value in evaluation for respiratory tract infections caused by *H. influenzae*.

Haemophilus spp. die rapidly in clinical specimens, and prompt transportation and processing are vital for their isolation and recovery. This is especially true of genital specimens submitted for *H. ducreyi*, which is extremely fastidious. Genital sites should first be cleansed with sterile gauze moistened with sterile saline before specimens are collected for the isolation of this organism. Next, a swab premoistened with sterile phosphate-buffered saline should be used to collect material from the base of the ulcer. As an alternative, pus can be aspirated from buboes if they are present. Direct plating on selective media at the bedside is preferred instead of using transport media. Because *Haemophilus* spp. are susceptible to drying, specimen processing in the laboratory should occur soon after collection for maximum recovery.

Because of the lack of one or more growth factors, most conventional media do not support the growth of *Haemophilus* spp. When attempting to isolate *H. influenzae*, CHOC agar is a commonly used medium incubated between 33° and 37° C in an atmosphere of 5% to 10% carbon dioxide (CO₂). It has been shown that CHOC agar supplemented with bacitracin (300mg/L) is an excellent medium for the isolation of *Haemophilus* spp. from respiratory specimens. Bacitracin is

added to reduce overgrowth of normal respiratory microbiota, a significant challenge to the isolation of *Haemophilus* spp. Growth on CHOC agar is usually seen after 18 to 24 hours of incubation.

Specimens submitted for *H. ducreyi* and *H. aegyptius* must be plated to special media because of their fastidious nature. For *H. aegyptius*, enriched CHOC agar supplemented with 1% IsoVitaleX (BD Diagnostic Systems, Sparks, MD) or Vitox (Oxoid, Basingstoke, UK) is required. Enriched CHOC medium is commonly used in clinical microbiology laboratories. *H. ducreyi* also grows on enriched CHOC medium, or a Nairobi biplate can be used. Nairobi biplate consists of GC agar base with 2% bovine hemoglobin and 5% fetal calf serum on one half and Mueller Hinton agar with 5% chocolate horse blood on the other. Both sides contain 3 mg/L of vancomycin. The use of GC agar (Gibco Laboratories, Grand Island, NY) containing 1% hemoglobin, 5% fetal calf serum, 1% IsoVitaleX, and 3 mg/L of vancomycin is also reported to be reliable. The use of vancomycin (most *H. ducreyi* are resistant) in the media helps reduce the growth of commensal biota from genital specimens and improves the detection of *H. ducreyi*. The plates for the recovery of this organism should be incubated in a 5% to 10% CO₂ atmosphere containing high humidity. In contrast with the optimal growth temperature (35° to 37° C) of the other *Haemophilus* spp., *H. ducreyi* grows best at 33° C. Cultures for *H. aegyptius* should be held for at least 4 days, and cultures for *H. ducreyi* should be held for at least 7 days before reporting a negative result.

Colony morphology

Most clinical specimens are plated onto a variety of culture media and examined after overnight incubation. Usually, SBA, CHOC agar, and MAC agar plates are inoculated simultaneously from clinical specimens from areas of the human body where *Haemophilus* organisms may be isolated. Colonies of *H. influenzae* on CHOC agar appear translucent, tannish, moist, smooth, and convex, with a distinct “mousy” or bleach-like odor. Fig. 18.3 shows the typical colony morphology of *H. influenzae*. The growth of *H. influenzae* biogroup *aegyptius* resembles *H. influenzae*. Encapsulated strains of *H. influenzae* grow larger and more mucoid than the NTHi strains. *Haemophilus* spp. do not grow on MAC agar. *Haemophilus* spp. sometimes grow on SBA plates around colonies of other bacterial species—a phenomenon known as *satellitism*, as discussed previously.

On CHOC agar, *H. parainfluenzae* colonies appear tannish and drier with a medium to large size compared with *H. influenzae*. On CHOC agar, *H. parahaemolyticus* resembles *H. parainfluenzae*; however, when grown on horse or rabbit blood agar, it is β -hemolytic, whereas *H. influenzae* is nonhemolytic. *H. ducreyi* appears as small, flat, smooth, nonmucoid, transparent to opaque colonies or appears tan or yellow on CHOC agar. Individual colonies can be pushed intact using a loop across the agar plate surface. They are difficult to pick up and produce a “clumpy” nonhomogeneous appearance when suspended in saline. Several publications have described in-house polymerase chain reaction (PCR) assays. The BioFire FilmArray (bioMérieux, Durham, NC) has a multiplex nucleic acid amplification meningitis/encephalitis panel for CSF that includes *H. influenzae*.

Fig. 18.3 Example of *Haemophilus influenzae* growing on chocolate agar. Note the tan mucoid colonies characteristic of encapsulated strains.

Microscopic morphology

With most *Haemophilus* spp., the microscopic morphology varies from small, gram-negative coccobacilli to long filaments (described as pleomorphic). The coccobacillary morphology is the more predominant form found in clinical specimens. Capsules of *H. influenzae* may be observed in Gram-stained direct smears as clear, nonstaining areas (“halos”) surrounding the organisms in purulent secretions. Because the organism is small and pleomorphic and often stains a faint pink, it can resemble the amorphous serous material (serumlike or proteinaceous background material) in Gram stains of clinical specimens.

Because of the low specificity and sensitivity of Gram stain, an acridine orange or methylene blue stain of the specimen may help detect *Haemophilus*. Fig. 18.4 illustrates the microscopic morphology of *H. influenzae* in a direct Gram-stained smear of CSF from a patient with meningitis. Fig. 18.5 is an example of a Gram-stained smear from an isolated colony of *H. influenzae*. Gram-stained smears for microscopic morphology of genital lesions or colonies for *H. ducreyi* may show pale-staining gram-negative coccobacilli arranged singly or in groups (clusters), commonly referred to as *school of fish* or *railroad tracks*, and loosely coiled clusters of organisms lined up in parallel or appearing as “fingerprints.”

Laboratory identification

The first clue that an isolate might belong to the genus *Haemophilus* is the growth of gram-negative pleomorphic coccobacilli in pure culture on CHOC agar, with no growth on SBA and MAC agar. Several tests can be used in the clinical laboratory for the identification of *Haemophilus* isolates, including testing for growth factors (X and V), oxidase, catalase, traditional biochemicals, and hemolysis on media containing rabbit or horse RBCs. In place of traditional biochemicals, several manual and automated commercial systems can be used to identify and biotype *Haemophilus* spp. within 4 hours. Recently, matrix-assisted laser desorption/ionization–time-of-flight

Fig. 18.4 Direct smear of *Haemophilus influenzae* in cerebrospinal fluid in a case of meningitis. Note the intracellular and extracellular gram-negative coccobacilli (arrows) ($\times 1000$).

Fig. 18.5 Gram stain of a *Haemophilus influenzae* colony. Bacilli are slightly more elongated than in direct smears ($\times 1000$).

(MALDI-TOF) mass spectrometry has demonstrated excellent identification of the HACEK organisms.

X factor and V factor requirements

Testing for X factor and V factor requirements using impregnated strips or disks is the traditional approach for identification of *Haemophilus* spp. Care must be taken not to transfer any X factor-containing medium to the agar plates used for X factor requirement testing; carryover can produce erroneous or inconclusive results, causing *H. influenzae* to be misidentified as *H. parainfluenzae* (see [Appendix D](#) on Evolve). [Figs. 18.6 to 18.8](#) illustrate the reactions obtained when testing for X factor and V factor requirements using impregnated strips. When *Haemophilus* spp. are grown anaerobically, they do not require heme but still require NAD. If an *H. influenzae* isolate was incubated anaerobically in this test, it could be misidentified as *H. parainfluenzae*. Of all species that require V factor, *A. segnis* is the only organism that is oxidase negative.

The *Haemophilus* ID Quad Plate (Thermo Fisher Scientific, Waltham, MA) contains four zones: media with X factor only, with V factor only, with X and V factors, and with X and V factors with horse RBCs. The *Haemophilus* isolate may

Fig. 18.6 This organism is identified as *Haemophilus influenzae* because it requires both X and V factors.

Fig. 18.7 This organism requires V factor only and is identified as *Haemophilus parainfluenzae*.

be identified based on the factors required for growth and the presence of hemolysis. *H. haemolyticus* is generally β -hemolytic on horse blood, whereas *H. influenzae* is negative. Misidentifying *H. haemolyticus* as *H. influenzae* may result in overtreatment because hemolysis is the major differentiating characteristic between the two species.

Porphyryn test

The **porphyrin** test is an alternative method for differentiating the heme-producing species of *Haemophilus*. The porphyrin test can be performed in agar, in broth, or on a disk. The principle of the test is based on the ability of the organism to convert the substrate δ -aminolevulinic acid (ALA) into porphyrins or porphobilinogen, which are intermediates in the synthesis of X factor. After incubation at 35° C for 4 hours, porphobilinogen is detected by the addition of *p*-dimethylaminobenzaldehyde (Kovac reagent). After addition of Kovac reagent, a red color forms in the lower aqueous phase if porphobilinogen is present. Porphyrins can be detected using an ultraviolet light with a wavelength of about 360 nm (Wood

Fig. 18.8 This organism is positive for X factor only. The probable species is *Aggregatibacter aphrophilus* because this species can appear to be hemin dependent on initial isolation.

lamp). Porphyrins fluoresce to a reddish orange color under ultraviolet light.

The main advantage of the porphyrin test is that X factor is not required, and the problem of carryover is eliminated. The disadvantage is that primary identification is based on a negative test result. In the case of *H. influenzae*, the ultraviolet light test is negative (no fluorescence), and no color change occurs after addition of Kovac reagent. Species that are porphyrin negative cannot synthesize heme and are X factor positive (require hemin) when the impregnated strip is used. *Haemophilus* spp. that can synthesize heme are porphyrin positive (X strip negative, do not require hemin). **Fig. 18.9** illustrates the positive result of the porphyrin test performed on agar. The Clinical and Laboratory Standards Institute (CLSI) developed abbreviated test guidelines for the identification of commonly isolated bacteria. Gram-negative bacilli or coccobacilli isolated from respiratory tract specimens or CSF that exhibit colonies larger than 1 mm on CHOC agar and no growth or satellitism on SBA and a negative porphyrin test can be identified as *H. influenzae*.

Biochemical tests

Biochemical tests, such as carbohydrate fermentation, can help further differentiate *Haemophilus* spp. In addition, indole, urease, and ornithine decarboxylase tests are used to biotype some *Haemophilus* spp. Numerous commercial multitest systems are available, including the RapID NH system (Thermo Fisher Scientific), Crystal Neisseria/*Haemophilus* system (BD Diagnostic Systems), and NH ID Card (bioMérieux). **Table 18.2** lists the differential tests for *Haemophilus* and *Aggregatibacter* spp. **Table 18.3** lists the tests that differentiate *H. influenzae* and *H. parainfluenzae* biogroups. Differentiating the biogroups is generally necessary only in epidemiology studies.

Treatment

Invasive *H. influenzae* infection often requires hospitalization. The recommended treatment of life-threatening illness caused by *H. influenzae* is cefotaxime or ceftriaxone. Alternative drugs

Fig. 18.9 Under ultraviolet light, the organism on the bottom is exhibiting a positive porphyrin reaction. The organism on the top is porphyrin negative.

include trimethoprim-sulfamethoxazole, imipenem, and ciprofloxacin. Chloramphenicol with ampicillin is also effective. Because of increased resistance to ampicillin, this drug should not be used alone for initial therapy. Non-life-threatening *H. influenzae* infection may be treated with amoxicillin-clavulanate, an oral second-generation or third-generation cephalosporin, or trimethoprim-sulfamethoxazole. For the treatment of *H. ducreyi*, azithromycin, ceftriaxone, ciprofloxacin, or erythromycin is recommended.

Increased resistance to ampicillin by *Haemophilus* spp. resulting from β -lactamase or, to a lesser extent, altered penicillin-binding proteins has been reported. In the United States, approximately 25% of NTHi isolates are β -lactamase positive. Several rapid tests to detect β -lactamase production are available, including the chromogenic cephalosporin test (Cefinase; BD Diagnostic Systems) and acidometric tests (see **Chapter 13**). A positive β -lactamase test means that the microorganism is resistant to ampicillin and amoxicillin.

In the chromogenic cephalosporin test, a disk impregnated with nitrocefin is moistened with a drop of water. Using a sterile loop, several colonies are smeared onto the disk surface, or forceps can be used to wipe the moistened disk across the colonies. If the β -lactam ring of nitrocefin is broken by the enzyme β -lactamase, a red color develops on the area where the culture was applied. The reaction usually occurs within 5 minutes.

In the acidometric test, a strip impregnated with benzylpenicillin and a pH indicator, bromcresol purple, is moistened with one or two drops of sterile distilled water. Using a sterile loop, several colonies are smeared onto the test strip. If the β -lactam ring of the benzylpenicillin is broken by β -lactamase, penicilloic acid is formed, causing a decrease in pH. This decrease in pH is demonstrated by a color change from purple (negative) to yellow (positive) on the strip within 5 to 10 minutes.

Antimicrobial susceptibility testing of *H. influenzae* should be limited only to isolates known to be clinically significant. In most cases, only testing for β -lactamase activity to assess ampicillin and amoxicillin efficacy is necessary. Because of the fastidious nature of the organism, special media and protocols must be followed if antimicrobial susceptibility testing is performed.

HACEK group

HACEK is an acronym consisting of the first initial of each genus represented in the group:

Haemophilus spp., e.g., *H. paraphrophilus*

Aggregatibacter actinomycetemcomitans, formerly *Actinobacillus actinomycetemcomitans*, and *A. aphrophilus*, formerly *H. aphrophilus*

Cardiobacterium hominis

Eikenella corrodens

Kingella spp.

Members of this group of gram-negative bacilli have in common fastidious nutritional requirements and enhanced growth with increased CO₂. Members of the genus *Cardiobacterium* are **capnophilic** (require CO₂). In contrast with *Haemophilus* spp., the latter four members of the HACEK group are considered more **dysgonic** (i.e., slower or poorer growing). Their predilection for attachment to heart valves, usually damaged or prosthetic, makes many of them an important cause of endocarditis that often involves the heart valves. The lesion (referred to as **vegetation**) is composed of fibrin, platelets, polymorphonuclear cells, monocytes, and microorganisms. Additional organisms that account for most cases of endocarditis are the viridans group of streptococci (most common after 1 year of age), *S. aureus*, *S. pneumoniae*, coagulase-negative staphylococci, *Abiotrophia* spp., and enterococci.

Members of the HACEK group include both fermentative and nonfermentative, gram-negative bacilli. All members can be normal biota of the oral cavity, which permits their introduction in the bloodstream and resultant infections. All

HACEK organisms are opportunists and generally require a compromised host. Risk factors for infective (bacterial) endocarditis include tooth extraction, history of endocarditis, gingival surgery, heart valve surgery, and mitral valve prolapse. Table 18.4 summarizes the key reactions and characteristics of HACEK and *Capnocytophaga* spp.

Aggregatibacter aphrophilus

A. aphrophilus (Greek *aphros* and *philia*: foam loving or desiring high concentration of CO₂) is one of the most prevalent species in the HACEK group involved in endocarditis. This organism has also been linked to bone and joint infections. Although it does not require CO₂, it does grow better in its presence. *A. aphrophilus* is found in dental plaque and gingival scrapings. Patients with infections present commonly with clinical features of fever, heart murmur, congestive heart failure, and embolism. *H. aphrophilus* and *H. paraphrophilus* have been reclassified into the single species, *A. aphrophilus*. This species contains V factor–dependent (see Fig. 18.7) and V factor–independent strains (Fig. 18.10). *A. aphrophilus* colonies are convex, granular, and yellow with an opaque zone near the center on CHOC agar. Figs. 18.11 and 18.12 illustrate the colony and microscopic morphology of *A. aphrophilus*.

Aggregatibacter actinomycetemcomitans

A. actinomycetemcomitans was formerly in the genus *Actinobacillus*. The remaining members of *Actinobacillus* include animal pathogens or animal endogenous biota that in general do not routinely cause human infections. Human

Table 18.4 Summary of key reactions and characteristics of HACEK and *Capnocytophaga* species

+, Positive; –, negative; V, variable.
^a*C. canimorsus* and *C. cynodegmi* are catalase and oxidase positive.

Fig. 18.10 An *Aggregatibacter aphrophilus* isolate that is not X factor dependent and is growing over the entire surface of a trypticase soy agar plate.

tissue infections have been attributed to bites by cattle, sheep, pigs, and horses or through contact with these animals. *A. actinomycetemcomitans* is divided into six serotypes (a to f) based on a surface polysaccharide, of which a, b, and c are the most common. The organism is found as normal oral microbiota in humans and is a major contributor to periodontitis (Fig. 18.13). Individuals with juvenile periodontal disease or other dental disease harbor the organism, and it can cause destruction of the alveolar bone that supports teeth in these individuals. *A. actinomycetemcomitans* has been isolated from blood, lung tissue, abscesses of the mouth and brain, and sinuses. It has been linked to subacute bacterial endocarditis with an insidious and protracted presentation. Major virulence factors include collagenase and a leukotoxin that is toxic to polymorphonuclear cells and monocytes.

A. actinomycetemcomitans grows better with increased CO₂. The isolates may require more than 24 hours for visible growth; a distinctive “star shape with four to six points” in the center of the colonies is often seen at 48 hours. The star shape is best observed after 48 hours by using $\times 100$ magnification under a light microscope when grown on a clear medium or a stereomicroscope at the highest magnification available. Fig. 18.14 depicts the colony morphology. In broth,

Fig. 18.11 *Aggregatibacter aphrophilus* growing on sheep blood agar.

Fig. 18.12 Gram stain morphology of *Aggregatibacter aphrophilus* ($\times 1000$).

Fig. 18.13 Advanced periodontitis. Periodontitis is inflammation of the periodontium caused by a complex reaction initiated when subgingival plaque bacteria are in close contact with the epithelium of the gingival sulcus. (From Murray, P. R., et al. [1994]. *Medical microbiology* [2nd ed.]. St. Louis: Mosby.)

Fig. 18.14 *Aggregatibacter actinomycetemcomitans* on sheep blood agar. The star-shaped centers of the colonies are not usually evident until after 48 hours of incubation and are best observed by using $\times 100$ magnification (light microscope) or a stereomicroscope.

the organism is granular and may adhere to the sides of the tube. Isolates are catalase positive and oxidase variable, do not grow on MAC agar, and are negative for X and V growth factor requirements, urease, indole, esculin, and citrate. *A. actinomycetemcomitans* is typically urease negative, which differentiates it from the members of the genus *Actinobacillus*. Glucose fermentation is positive (with or without gas), although the addition of serum to the carbohydrate-containing medium is often necessary to demonstrate fermentation. Xylose, mannitol, and maltose fermentation are variable. The isolates do not ferment lactose or sucrose.

A. actinomycetemcomitans demonstrates sensitivity to penicillin in vitro, although this agent is not always successful clinically, and resistance to ampicillin is common. Isolates are typically susceptible to aminoglycosides, third-generation cephalosporins, quinolones, chloramphenicol, and tetracycline. Resistance to vancomycin and erythromycin is common. Usual treatment for endocarditis is with penicillin and an aminoglycoside.

Cardiobacterium hominis

The genus *Cardiobacterium* contains two species: *C. hominis* and *C. valvarum*. Both are pleomorphic, nonmotile, fastidious, gram-negative bacilli found as normal microbiota of the nose, mouth, and throat and may be present in the gastrointestinal tract. Oral infections or dental procedures usually precede endocarditis. The usual clinical manifestation is endocarditis, often manifesting with very large vegetations and no demonstrable fever. It infects the aortic valve more frequently compared with the other HACEK organisms. Rarely, *C. hominis* has been associated with meningitis.

Gram-stained smears of the bacilli often show false gram-positive reactions in parts of the cells. The organisms tend to form rosettes, swellings, long filaments, or sticklike structures in yeast extract. They grow slowly on SBA and CHOC agar and fail to grow on MAC agar. Incubation in a humid atmosphere (either aerobic or anaerobic) with 5% CO₂ is required for growth. Figs. 18.15 and 18.16 illustrate the colony and microscopic morphology. On agar, "pitting" can be produced. *C. hominis* is a fermenter, but as with *A. actinomycetemcomitans*, reactions may be weak, and serum might be needed. Isolates are oxidase positive, catalase negative, and indole positive; the latter two traits help differentiate them from *Aggregatibacter* spp. *C. hominis* is negative for

Fig. 18.15 Growth of colonies of *Cardiobacterium hominis* over 48 hours on sheep blood agar.

Fig. 18.16 Gram-stained smear of *Cardiobacterium hominis* showing typical "rosettes" (×1000).

urease, nitrate, gelatin, and esculin. Sensitivity can be seen to β -lactams, chloramphenicol, and tetracycline with variable response to aminoglycosides, erythromycin, clindamycin, and vancomycin. Usual therapy includes penicillin and an aminoglycoside.

Eikenella corrodens

E. corrodens is a member of the normal biota of the oral and bowel cavities. Most infections associated with this organism have been polymicrobial and often occur as a result of trauma, especially after human bites or fights (i.e., "clenched fist wounds," or after the skin has been broken by human teeth). Poor dental hygiene or oral surgery has also been associated with infections. It is an opportunistic pathogen, especially in immunocompromised individuals. *E. corrodens* has been reported as the cause of adult periodontitis, meningitis, empyema, pneumonia, osteomyelitis, arthritis, and postoperative tissue infections. In those with drug addiction, it has been implicated in cellulitis as a result of direct inoculation of the organisms into the skin after oral contamination of needle paraphernalia (because of licking the needle for cleaning, instead of sterilizing, and for good luck). *E. corrodens* shows a predilection for attachment to heart valves and

Fig. 18.17 Growth of *Eikenella corrodens* on chocolate agar. (Compare this growth with *Capnocytophaga* in Fig. 18.20.)

Fig. 18.18 Gram stain morphology of *Eikenella corrodens* (×1000).

causes endocarditis, although it is probably the least common isolate of the HACEK group in adult infectious endocarditis.

E. corrodens isolates are fastidious, gram-negative coccobacilli that grow best under conditions of increased CO₂ with hemin. They are nonmotile, oxidase positive, and asaccharolytic. They are catalase negative and often produce a yellow pigment. About 45% of the isolates of *E. corrodens* "pit" (make a depression) or corrode the surface of the agar. Figs. 18.17 and 18.18 illustrate the colony and microscopic morphology. Although they are nonhemolytic on SBA, a slight greening effect secondary to growth may occur around the colonies. A chlorine bleach-like odor from the agar surface may be obvious. Isolates do not usually grow on MAC agar or eosin-methylene blue (EMB) agar. In broth media, *E. corrodens* may adhere to the sides of the tube and produce granules. Typically, *E. corrodens* is resistant to clindamycin and narrow-spectrum cephalosporins. In vitro, isolates demonstrate sensitivity to penicillin, ampicillin, cefoxitin, chloramphenicol, carbenicillin, and imipenem.

Kingella

The genus consists of six species: *Kingella kingae*, *K. denitrificans*, *K. negevensis*, *K. oralis*, *K. bonacorsii*, and *K. potus*. *Kingella*

spp., especially *K. kingae*, are recognized as important pathogens in the pediatric population and have a predilection for bones and joints. It appears to be the most common cause of osteoarthritis infection in children younger than 4 years of age. *K. kingae*, a member of the normal oropharynx microbiota, has also been associated with endocarditis, particularly in immunocompromised patients. Isolates have been obtained clinically from blood, bone, joint fluid, urine, and wounds. *K. denitrificans* has been associated with endocarditis. Poor dental hygiene or oral surgery is associated with infection by *Kingella* spp.

Members of the genus *Kingella* are coccobacillary to short bacilli with squared ends that occur in pairs or short chains (Fig. 18.19). They tend to resist decolorization on Gram stain. *Kingella* spp. are typically nonmotile. They are nutritionally fastidious, oxidase-positive, catalase-negative, and ferment glucose and other sugars but with no gas.

Kingella spp. can grow on *Neisseria* selective agar (e.g., modified Thayer-Martin [MTM] medium) and can resemble *Neisseria gonorrhoeae* if the isolate does not pit the agar as many strains do. *K. denitrificans*, like *N. gonorrhoeae*, produces acid from glucose. Gram-stain morphology of a rod with square ends and in chains and a negative catalase test result aid in distinguishing *Kingella* spp. from *N. gonorrhoeae*. Isolates with the following characteristics meet the CLSI abbreviated test requirements for *K. kingae*: gram-negative, short, coccoid bacilli forming large white-to-beige β -hemolytic colonies on SBA, no growth on MAC agar, catalase negativity, and oxidase positivity. *K. denitrificans* is positive for glucose fermentation and nitrate reduction and might grow at 42° C. *K. denitrificans* has two types of colonies: a smooth, convex type and a spreading, corroding type.

K. kingae weakly ferments glucose and maltose but is negative for sucrose. In contrast with other *Kingella* spp., it may produce a yellow-brown pigment. *K. kingae* has two types of colony morphologies: a spreading, corroding colony or a smooth, convex, and β -hemolytic colony. The hemolysis may appear beneath the colony or in close proximity after 24 hours. After 48 hours of incubation, the hemolysis is more evident. Isolates of *Kingella* spp. are usually susceptible to most agents, including penicillin.

Fig. 18.19 Gram-stained smear of *Kingella kingae* illustrating the plump bacilli in chains and tendency to resist decolorization. Compare with other members of the HACEK group ($\times 1000$).

Capnocytophaga

Capnocytophaga belongs to the family Flavobacteriaceae and includes bacteria previously called DF-1 and DF-2 (dysgonic fermenters). The genus consists of at least 14 species, 6 of which are normal microbiota of the oral cavity of humans and have been associated with septicemias and other human infections. *Capnocytophaga* spp. are not as commonly involved in endocarditis as they are in septicemia, notably in patients with neutropenia. Common sites of clinical isolation include blood cultures from patients who have neutropenia with oral ulcers (source of the *Capnocytophaga*), soft tissue infections, peritonitis, and endocarditis. *C. ochracea* is the most common clinical isolate. *C. canimorsus* and *C. cynodegmi* are normal inhabitants of the oral cavity of dogs and cats. *C. canimorsus* can cause a fulminant, life-threatening septicemia in humans, particularly in patients with asplenia or alcoholism, after a dog or cat bite, or through continuous contact. This etiologic agent should be considered in patients who have a history of dog bites or saliva transfer and progressive illness.

Capnocytophaga spp. are fastidious, facultatively anaerobic, gram-negative bacilli and require increased CO₂ for growth and isolation from blood cultures. They are thin and often fusiform (pointed ends) resembling *Fusobacterium* spp.; spindle-shaped, coccoid, and curved filaments may be also seen. Although flagella are usually absent, *Capnocytophaga* can produce gliding motility on solid surfaces. On agar, colonies are often adherent and produce a yellow-orange pigment; they can resemble colonies of *E. corrodens*. Most *Capnocytophaga* isolates are nonhemolytic except for *C. haemolytica* (β -hemolytic). Figs. 18.20 and 18.21 depict the colony and microscopic morphology.

Capnocytophaga spp. ferment sucrose, glucose, maltose, and lactose, although triple sugar iron agar (TSIA) may be negative without enrichment. These organisms are negative for most biochemical reactions, including indole. The six normal inhabitants of the human oral cavity—*C. ochracea*, *C. gingivalis*, *C. sputigena*, *C. haemolyticus*, *C. leadbetteri*, and *C. granulosa*—are all oxidase and catalase negative. *C. canimorsus* and *C. cynodegmi* are oxidase and catalase positive. *Capnocytophaga* spp. are susceptible to imipenem, erythromycin, clindamycin,

Fig. 18.20 Growth of *Capnocytophaga* organisms on chocolate agar. Note the spreading away from the center of the colony. (Compare this growth with *Eikenella* in Fig. 18.17).

Fig. 18.21 Gram stain morphology of *Capnocytophaga* sp. (×1000). Note the thin fusiform bacilli.

tetracycline, chloramphenicol, quinolones, and β -lactams, but they are resistant to the aminoglycosides. For *C. canimorsus* and *C. cynodegmi* infections, penicillin is the drug of choice.

Pasteurella

Pasteurellosis, infection with *Pasteurella* spp., is a **zoonosis**—a disease that humans acquire from exposure to infected animals or products made from infected animals. Although systemic (septicemia, arthritis, endocarditis, osteomyelitis, meningitis) and pneumonic forms are possible, soft tissue (cutaneous) infection, frequently resulting from animal bites, is the most common presentation. These wounds can become infected with *Pasteurella* spp. because these organisms often reside in the respiratory tracts and oral cavities of birds and mammals. Cutaneous infections can quickly progress, resulting in inflammation and exudate production. Although *Pasteurella* infections can result from a variety of animal bites, they often occur as the result of feline bites.

At least 17 species of *Pasteurella* have been identified; based on deoxyribonucleic acid (DNA) hybridization, several species are more closely related to other genera, such as *Actinobacillus*. *Pasteurella multocida* is the most frequently isolated species and includes four subspecies: *multocida*, *septica*, *tigris*, and *gallicida*. *P. multocida* also consists of five serogroups (A, B, D, E, and F) defined by capsular antigens. *P. canis*, associated with dogs, and *P. stomatis* and *P. dagmatis*, both associated with dogs and cats, are also isolated infrequently from humans.

Pasteurella spp. are gram-negative, nonmotile, facultative, anaerobic coccobacilli that appear ovoid, filamentous, or as bacilli. **Bipolar staining** (safety pin appearance when the poles of the cells are more intensely stained) is frequently observed. These bacteria are catalase and oxidase (most isolates) positive and ferment glucose with weak to moderate acid production without gas.

All *Pasteurella* spp. grow on SBA and CHOC agar, producing grayish colonies (Fig. 18.22). Conversely, MAC agar does not support the growth of most *Pasteurella* spp. Growth on SBA in the absence of satellitism or in pure culture combined with bipolar staining may differentiate *Pasteurella* from *Haemophilus*. *P. multocida* produces nonhemolytic colonies on SBA that may appear mucoid after 24 hours of incubation at 35° C followed by the production of a narrow green-to-brown

Fig. 18.22 *Pasteurella multocida* growing on sheep blood agar and chocolate agar. The MacConkey agar plate is negative for growth.

halo around the colony after 48 hours. Table 18.5 lists the various growth characteristics and biochemical reactions that can be useful in the differentiation of *Pasteurella* spp. associated with human infections.

Brucella

Brucellosis, infection with bacteria from the genus *Brucella*, is an important zoonotic disease that is found throughout the world. There are eight named terrestrial species. However, on the basis of genetic similarity, it has been proposed that there be a single species with six biovars. The most prevalent species reported in terrestrial wildlife is *B. abortus*. The four species that are most commonly associated with human illness are *B. melitensis*, *B. abortus*, *B. suis*, and *B. canis*. The four other species are *B. ovis*, *B. neotomae*, *B. microti*, and *B. papionis*. In recent years, additional species have been isolated from marine mammals. Because of their potential application in bioterrorism, *Brucella* spp. are considered category B **select biological agents** by the CDC. Category B agents are easy to disseminate and cause moderate morbidity but low mortality. U.S. Federal Code 42CFR72.6 describes the requirements for possession and transfer of select biological agents. For more information about biological threat agents, see Chapter 30. Brucellosis is a CDC-reportable disease because the diagnosis can have public health implications. Approximately 100 cases are reported annually.

Brucellosis has been described by both the disease course (undulant fever) and the geographic locations where cases have occurred (Mediterranean, Crimean, and Malta fevers). Certain subpopulations are at higher risk of contracting brucellosis, such as individuals exposed to animals and animal products (e.g., veterinarians, hunters) and laboratory workers. Brucellosis is acquired through aerosol, percutaneous, and oral routes of exposure. Oral exposure can occur by aerosol or ingestion of unpasteurized milk. Although direct person-to-person transmission is considered rare, cases resulting from sexual contact and breast-feeding have been reported.

The resulting clinical presentation appears to be similar for all exposure routes. The three clinical stages of brucellosis, based arbitrarily on disease duration, are the acute, subchronic, and chronic stages. Symptoms of acute infection

Table 18.5 Differential characteristics of *Pasteurella* species associated with human infections

Species/ subspecies	Normal habitat	Hemolysis	Oxidase	Catalase	ODC	Indole	Growth on MacConkey	Urease	Comments
<i>P. multocida</i>	Oral cavities of healthy domestic dogs, cats, and other animals (swine, horses, cattle)	–	+	+	+	+	–	–	Most common isolate from human specimens; most infections are associated with dog and cat bites and scratches; can cause respiratory tract infections, including lung abscesses, pneumonia, empyema, and tonsillitis; usually underlying disease present or immune complications; differentiated by acid production from dulcitol and sorbitol; rare clinical isolates, primarily of veterinary interest
<i>P. pneumotropica</i>	Respiratory tract of dogs, cats, and some rodents	–	+	+	+	+	V	+	Human infections acquired mostly through dog and cat bites
<i>P. dagmatis</i>	Respiratory tract of dogs and cats	–	+	+	–	+	–	+	Human infections caused by bites and scratches of dogs and cats
<i>P. stomatis</i>	Oropharyngeal biota of dogs and cats	–	+	+	–	+	–	–	Caused by bites
<i>P. canis</i>	Biotype I is found in the oral cavity of dogs	–	+	+	+	+	–	–	Wound infections caused by dog bites
<i>P. bettyae</i>	Isolated from genitourinary tract including vagina, cervix, Bartholin glands, and amniotic fluid	–	V	–	–	+	V	–	Pathogen may be sexually transmitted; formally known as CDC group HB-5

+, Greater than 90% positive; –, greater than 90% negative; CDC, Centers for Disease Control and Prevention; ODC, ornithine decarboxylase; V, 20% to 80% positive.

are nonspecific (fever, malaise, headache, anorexia, arthralgia, myalgia, and back pain) and usually occur within 1 to 4 weeks of exposure. Brucellosis is a systemic, deep-seated disease resulting in various long-term sequelae. Mortality is low and generally results from cardiac disease. The subchronic or undulant fever form of the disease typically occurs within 1 year of exposure and is characterized by undulating fevers (characterized by body temperatures that rise in the afternoon and evening and fall in the morning), arthritis, and epididymo-orchitis (inflammation of the epididymis and testis). The chronic form commonly manifests 1 year after exposure with symptoms such as depression, arthritis, and chronic fatigue syndrome.

Brucellae are small gram-negative, aerobic, nonmotile, unencapsulated bacteria that may appear as coccobacilli or bacilli. Under optimal growth conditions on agar, smooth, raised, and translucent colonies appear (Fig. 18.23). The bacteria are facultative intracellular pathogens that can reside within mononuclear phagocytic cells. It can be difficult to diagnose brucellosis through direct examination of a clinical sample, most often blood or bone marrow, and the ability for direct isolation and culture can vary between acute and

chronic manifestations. The bacteria are sometimes recovered from CSF, synovial fluid, pleural fluid, and abscesses. Of acute cases, 50% to 80% yield positive blood cultures, whereas only 5% of chronic cases produce positive cultures. As a result, serologic tests are frequently used, in conjunction with patient history and disease status, to diagnose brucellosis.

Brucella spp. can vary in their requirement for CO₂. They grow on SBA and CHOC agar and can be isolated on MTM or Martin-Lewis media from contaminated specimens. Growth usually appears within 24 to 48 hours, and plates should be held for 4 days before being reported as negative. Brucellae are oxidase and catalase positive and are urease positive within 2 hours (Table 18.6). These tests can also differentiate brucellae from similar organisms (e.g., *Bordetella bronchiseptica*, *Acinetobacter* spp., and *H. influenzae*) when combined with growth on SBA, colony morphology, specimen source, and testing for X factor and V factor requirements (Table 18.7). MALDI-TOF mass spectrometry can be used for identification of *Brucella* species if the organism is included in the database being used (e.g. Bruker's biosecurity-relevant library). Members of *Brucellae* have been commonly

misidentified as *Oligella ureolytica*, *Psychrobacter phenylpyruvica*, and *Ochrobactrum anthropi* on MALDI-TOF mass spectrometry libraries that do not include *Brucella* species. *Brucella* species can be identified by real-time PCR and subtyped into biovars using molecular biology techniques.

Fig. 18.23 *Brucella melitensis* colonies on sheep blood agar appear smooth, raised, and translucent. (From the CDC Public Health Image Library. <http://www.phil.cdc.gov/phil>. Courtesy Larry Stauffer, Oregon State Public Health Laboratory.)

Because of the aerosol mode of transmission, *Brucella* spp. should be handled under biosafety level 3 conditions (e.g., within a biological safety cabinet). Approximately 2% of all reported cases of brucellosis are acquired in the laboratory, illustrating the risk of infection to clinical laboratory personnel. The chance of acquiring an infection from a laboratory exposure ranges from 30% to 100% and depends on a range of factors.

Francisella

According to the current taxonomic classification, there are about 14 species in the genus *Francisella*. Although *F. tularensis* has been implicated in most human infections, *F. novicida* and *F. philomiragia* have also been known to infect patients with immune-compromising conditions. *F. tularensis* has four subspecies *tularensis* (type A), *holarctica* (type B), *novicida*, and *mediasiatica*. *F. tularensis* subsp. *tularensis* causes the most severe disease; *F. tularensis* subsp. *holarctica* produces a disease similar to that by *F. tularensis* subsp. *tularensis*, but infections are rarely fatal.

Tularemia, which is infection with bacteria from the genus *Francisella*, is a zoonotic disease and has many other names, including *rabbit fever*, *deerfly fever*, *lemming fever*, and *water rat trappers' disease*. Tularemia can be contracted through ingestion, inhalation, arthropod bite (e.g., ticks, biting flies), or contact with infected tissues. Clinical presentation can assume various forms and is influenced by the route of bacteria

Table 18.6 Differential characteristics of *Brucella* species associated with human infections

<i>Brucella</i> species	Natural hosts	Serum agglutination (patient antibodies)	H ₂ S (lead acetate)	Urease	CO ₂ (enhanced growth)	Inhibition of growth in dyes

exposure. The most common clinical form, reported in 45% to 80% of cases, is ulceroglandular, in which an ulcer forms at the site of inoculation and is followed by an enlargement of the regional lymph nodes. Tularemia can also occur in pneumonic (contracted via the inhalation route), glandular, oropharyngeal, oculoglandular, and typhoidal forms. Case fatality rates for tularemia in the United States range from 2.3% to 9%. *F. tularensis* is a CDC category A select biological agent. Category A agents are described as posing a risk to national security because they can be spread through person-to-person contact or are easily disseminated and result in high mortality rates, leading to a potentially great public health impact and public panic. Similar to brucellosis, tularemia is a CDC-reportable disease, and about 100- to 200 cases are reported annually.

The preferred specimen for isolation of *Francisella* spp. depends on clinical manifestations. Blood is an acceptable specimen for all forms; however, cultures can be negative early in the course of the infection. *Francisella* spp. appear as small, nonmotile, gram-negative bacilli or coccoid bacteria and are strictly aerobic. Similar to *Brucella* spp., *Francisella* are also facultative intracellular parasites. *Francisella* spp. are fastidious and require supplementation with cysteine, cystine, or thiosulfate for growth on successive passage. CHOC, MTM, and buffered charcoal yeast extract (BCYE) agars and thioglycollate broth may be used. However, because of the risks of laboratory infections from aerosols, broth cultures are not recommended. MAC and EMB agars do not support *F. tularensis* growth. Because of slow growth rates, *F. tularensis* colonies may not be visible before 48 hours of incubation at 35° C. Plates should be checked daily for 14 days. Once visible, gray-white, raised colonies with a smooth appearance are seen (Fig. 18.24).

F. tularensis is oxidase, urease, and satellite or X and V test negative and weakly positive for catalase and β -lactamase activity. Additionally, clinical symptoms, patient exposure in geographic locations where tularemia is endemic, and

serology are used to diagnose *F. tularensis* infection. A presumptive identification can be made by a positive test result in any one of the following assays: direct fluorescent antibody (DFA), immunohistologic staining with monoclonal antibody, PCR, slide agglutination, or single serology test. Confirmation requires culture identification or a fourfold increase in antibody titer. MALDI-TOF mass spectrometry has been shown to be an accurate method to identify *Francisella* strains, including the subspecies of *F. tularensis*.

F. tularensis is a highly infectious agent with as few as 50 organisms causing an infection through the cutaneous (ulceroglandular) or inhalation (pneumonic) routes and has been the cause of many laboratory-acquired infections. Three Boston University scientists were accidentally infected while working with a fully virulent strain. Laboratory personnel should use appropriate laboratory safety techniques and precautions. Biosafety level 3 conditions should be implemented when working with suspected *F. tularensis* samples.

Legionella

In 1976 during an American Legion convention in Philadelphia, 221 persons developed pneumonia, and 34 of them died of a mysterious disease. *Legionella pneumophila*, the causative agent of this outbreak, became the first named member of the family Legionellaceae, which now contains three genera: *Legionella*, *Fluoribacter*, and *Tatlockia*. The genus *Legionella* includes over 60 species and more than 70 serogroups. The primary human pathogen, *L. pneumophila*, contains 15 serogroups. Almost one half of the named species have been isolated from human clinical specimens.

The identification of *Legionella* from patient specimens can be achieved in most microbiology laboratories with the use of commercial media and other diagnostic methods. An understanding of the microscopic and colony morphology of the *Legionella* spp., their nutritional requirements, the pathogenesis, and the capabilities of various commercial laboratory tests enables clinical microbiologists to reliably identify these microorganisms.

General characteristics

Approximately 26 species of *Legionella* have been isolated from humans. They are ubiquitous gram-negative bacilli acquired primarily through inhalation from environmental sources. Many species can survive inside free-living amoebae. Infected patients can present with a wide variety of conditions. The laboratory diagnosis of *Legionella* infection typically depends on one or more of the following methods:

- Isolation using special media
- MALDI-TOF mass spectrometry
- Urine antigen detection
- Fluorescent antibody staining
- Nucleic acid amplification (e.g., PCR)
- Serology

Virulence factors

The most significant virulence factor of the legionellae is the ability to exist as intracellular pathogens, in amoebae and

Fig. 18.24 *Francisella tularensis* colonies grown on chocolate agar. After 72 hours of incubation, gray-white, raised colonies with a smooth appearance are visible. (From the CDC Public Health Image Library. <http://www.phil.cdc.gov/phil>. Courtesy Larry Stauffer, Oregon State Public Health Laboratory.)

mammalian cells. The bacteria survive inside phagosomes and prevent phagolysosome formation. *Legionella* spp. cause intracellular infections in humans and spread cell to cell. Differing presentations of *Legionella* spp. infection may be influenced by several factors, including the organism's ability to enter, survive, and multiply within the host's cells, especially bronchoalveolar macrophages, and the ability to produce proteolytic enzymes.

Infections caused by *Legionella*

Infections caused by *Legionella* spp. produce a spectrum of symptoms ranging from acute febrile disease with pneumonia (**Legionnaires' disease**), influenza-like febrile disease (**Pontiac fever**), and asymptomatic infection. The mode of transmission and the number of infecting organisms in the inoculum play a role in the clinical features of the infection. In addition, host factors, such as a suppressed immune system, chronic lung disease, alcoholism, and heavy smoking, predispose individuals to Legionnaires' disease. *Legionella* spp. are transmitted to human hosts from environmental sources, primarily via aerosolized water particles or gardening materials in the case of soil-associated *L. longbeachae*. Transmission between humans has not been demonstrated.

Legionnaires' disease

Legionnaires' disease typically manifests in three major patterns: (1) sporadic cases, which are most common and usually occur in the community; (2) epidemic outbreaks, characterized by short duration and low attack rates; and (3) healthcare-associated clusters, occurring in compromised patient populations. Pneumonia is the predominant manifestation of Legionnaires' disease, and the organisms are among the top four causes of community-acquired bacterial pneumonia. *S. pneumoniae* is the most common cause of bacterial pneumonia. *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, and *Legionella* produce symptoms different from *S. pneumoniae*, causing a disease sometimes referred to as **atypical pneumonia**. The mortality rate for Legionnaires' disease is 15% to 30% and may approach 50% in patients with healthcare-associated pneumonia if the correct diagnosis is not made early.

L. pneumophila serogroup 1 accounts for most cases of Legionnaires' disease, approximately 95%. The incubation period is 2 to 14 days, with a median of about 4 days, and patients typically present with a nonproductive cough, fever, headache, and myalgia. Later, as pulmonary infiltrates develop, sputum may be bloody or purulent. Rales, dyspnea, and shaking chills are clinical manifestations of progressing disease. Dissemination via the circulatory system can lead to extrapulmonary infections with or without pneumonia. Infections of the kidneys, liver, heart, CNS, lymph nodes, spleen, and bone marrow and cutaneous abscesses have been described. Bacteremia, renal failure, liver function abnormalities, watery diarrhea, nausea, vomiting, headache, confusion, lethargy, and other CNS abnormalities have been associated with these infections.

Pontiac fever

The nonpneumonic form of legionellosis, Pontiac fever, usually has a short incubation period of about 2 days. Patients

are previously healthy individuals who complain of flulike symptoms of fever, headache, and myalgia that last 2 to 5 days and then subside without medical intervention. No deaths have been reported. Studies suggest that the disease might be caused by inhalation of a bacterial toxin, such as endotoxin, or an acute allergic reaction to a bacterium. It is unclear if *Legionella* spp. play a role in this condition.

Epidemiology

Approximately 5000 cases of legionellosis are reported annually in the United States; however, many cases likely go undiagnosed. Physicians might not suspect *Legionella* spp., and many laboratories do not routinely culture for these agents. The CDC estimates an incidence of 18,000, and the number of cases has been increasing since 2000. *Legionella* spp. are responsible for 2% to 15% of community-acquired pneumonias in the United States annually. These microorganisms are also associated with healthcare-associated infections, often linked to contaminated equipment and water lines.

Members of the family Legionellaceae are found worldwide, occurring naturally in aquatic sources, such as lakes, rivers, hot springs, and mud. *L. longbeachae* is notable because human infections are associated with exposure to gardening materials, such as compost and potting soil, and constitutes a significant source of infection in New Zealand and Australia. Some species have been recovered only from environmental sources. Because *Legionella* spp. can tolerate chlorine concentrations of 3mg/L, they resist water treatment and subsequently gain entry into and colonize human-made water supplies and distribution systems. Hot water systems, cooling towers, and evaporative condensers are major reservoirs. Other sources include cold water systems, ornamental fountains, whirlpool spas, humidifiers, respiratory therapy equipment, and industrial process water. The factors that contribute to the ability of *Legionella* spp. to colonize these sources include:

- The ability to multiply over the temperature range of 20° to 43° C and survive for varying periods at 40° to 60° C
- The capacity to adhere to pipes, rubber, plastics, and sediment and persist in piped water systems, even when flushed
- The ability to survive and multiply within free-living protozoa and in the presence of commensal bacteria and algae

Laboratory diagnosis

Several methods, such as direct examination, culture, and antigen and antibody detection, are available for the laboratory diagnosis of infections caused by *Legionella* spp. Legionnaires' disease is best diagnosed using a combination of culture and urine antigen detection. Most laboratories use more than one method to maximize their diagnostic capabilities. Because of low sensitivity and false-positive test results from cross-reaction with other bacteria, DFA testing (see Fig. 18.28, later) is no longer recommended. A multiplex PCR pneumonia panel (BioFire FilmArray) that includes *L. pneumophila* along with 32 other targets has been approved by the U.S. Food and Drug Administration (FDA). Reference laboratories using laboratory-developed nucleic acid amplification tests have reported

sensitivities of 80% to 100% for *L. pneumophila* in lower respiratory tract specimens and specificities of greater than 90%. Diagnosis of Pontiac fever is usually based on laboratory findings, environmental studies, and epidemiology. Some outbreaks seemed linked to *L. pneumophila* serogroup 1. The *Legionella* urinary antigen test is commonly used for the diagnosis of Legionnaires' disease, but based on various studies, this test has not been useful for Pontiac fever.

Specimen collection and handling

Specimens for culture and direct examination commonly include sputum, bronchoalveolar lavage, and bronchial washings. Sputum scoring systems of expectorated sputum are not advised because of limited purulence. Other tissues or fluids, such as pleural fluid, are generally acceptable when suspicion is high. Small pieces of tissue may be overlaid with sterile water for transport to the laboratory; however, saline or buffer should not be used because of the inhibitory effects of sodium on *Legionella* spp. When delays of more than 2 hours between collection and processing are unavoidable, specimens should be refrigerated to avoid overgrowth of contaminating microbiota. It is recommended to freeze specimens at -70°C if processing will be delayed for several days.

Automated blood cultures are often insensitive, although lysis centrifugation using the Isolator system (Wampole Laboratories, Cranbury, NJ) is a good alternative, albeit labor-intensive. Urine is an important specimen to be collected for antigen detection, but it only detects *L. pneumophila* serogroup 1. Specimens are collected in sterile, leakproof containers. Specimens can be held at room temperature for a few hours; however, if processing is delayed, they should be stored at 2° to 8°C or frozen at -20°C . Environmental sources may be cultured during epidemiologic investigations, but this is normally a public health rather than a clinical or diagnostic function.

Microscopic examination

Legionella spp. are pleomorphic, weakly staining, gram-negative bacilli that are approximately 1 to $2\mu\text{m} \times 0.5\mu\text{m}$ in size. Extending the safranin counterstaining time to at least

10 minutes can enhance the staining intensity of the organisms. *L. micdadei* is weakly acid fast in tissue and stains best with the modified Kinyoun procedure (see Chapter 7). Other stains, including Diff-Quik (Baxter Scientific, Kansas City, MO) and Giemsa, can be used to facilitate observation of the organisms.

Nonspecific staining methods are most useful for examination of specimens from normally sterile sites. The faint-staining, pleomorphic gram-negative bacilli can be found outside of and within macrophages and segmented neutrophils (Fig. 18.25). The modified Kinyoun procedure can be used for tissue if *L. micdadei* is suspected.

Isolation and identification

Isolation methods

The most important test for Legionnaires' disease is culture of the organism. This should always be attempted, even when employing a rapid test such as urine antigen detection. Acid treatment of specimens contaminated with other bacteria, such as sputum, before inoculation enhances isolation of *Legionella* spp. (Fig. 18.26). In this procedure, an aliquot of the specimen is first diluted 1:10 with 0.2N potassium chloride-hydrochloric acid (KCl-HCl) (pH 2.2) and allowed to stand for no more than 4 minutes. The medium is then inoculated with a portion of the acid-treated specimen. Even specimens from normally sterile sites should be diluted 1:10 in tryptic soy broth or distilled water to dilute microbial inhibitors, such as complement, antibodies, and antimicrobial agents.

Legionella spp. are fastidious, aerobic bacteria that do not grow on SBA and require L-cysteine for growth. Tiny colonies may appear on CHOC agar that contains L-cysteine; however, BCYE with 0.1% α -ketoglutaric acid (BCYE α) agar is best for *Legionella* isolation. BCYE α agar is available commercially as nonselective and selective media, and both should be used for optimal isolation. Selective BCYE α media contain polymyxin B, anisomycin (an antifungal agent), and either vancomycin or cefamandole (e.g., BMPA, which contains cefamandole, polymyxin B, and anisomycin). Although selective medium improves recovery of *Legionella* spp. from highly contaminated specimens, it can inhibit growth of some *Legionella* spp.; therefore it should not be used alone. Inoculated media are incubated at 35°C in air; increased CO_2 can enhance the growth of some of the more fastidious species. *Legionella* spp. colonies are generally visible within 3 to 5 days, although some rarely isolated species might require 14 days.

Colony morphology

On BCYE α agar, colonies appear as grayish white or blue-green, convex, and glistening, measuring approximately 2 to 4 mm in diameter. When colonies are viewed with a dissecting microscope illuminated from above, they reveal a characteristic appearance (Fig. 18.27). The central portion of young colonies has a "ground-glass" appearance, light gray and granular, whereas the periphery of the colony has pink or light blue or bottle green bands with a furrowed appearance. Plates should be examined daily because older colonies lose these characteristic features and may be mistaken for other bacteria. Although some species autofluoresce with a long-wave ultraviolet light (366 nm), the variety of

Fig. 18.26 **A**, Nonselective buffered charcoal yeast extract with 0.1% α -ketoglutaric acid (BCYE α) agar plate inoculated with a sputum specimen. Note overgrowth of respiratory biota. **B**, Selective BCYE α agar plate inoculated with the same sputum specimen, which has been acid washed before inoculation. Much of the respiratory biota has been eliminated. *Legionella* colonies are the smallest ones (arrow) in the first quadrant. (Courtesy Richard Brust.)

Fig. 18.27 **A**, A *Legionella pneumophila* colony on buffered charcoal yeast extract agar with 0.1% α -ketoglutaric acid after 3 days of incubation, viewed with a dissecting microscope ($\times 20$). **B**, The same colony after 4 days of incubation. **C**, The same colony after 5 days of incubation. **D**, The same colony after 7 days of incubation.

BOX 18.1 Common phenotypic characteristics of *Legionella* species

- Slow growth (3–5 days)
- Characteristic “ground-glass” colony morphology
- Lightly staining, gram-negative bacillus
- Requires L-cysteine for primary isolation
- No growth on unsupplemented sheep blood agar
- Asaccharolytic
- Catalase or oxidase: weakly positive

colors and number of species may limit the utility in a typical clinical laboratory.

Identification methods

Conventional methods

The physical and biochemical properties of *Legionella* spp. are listed in Box 18.1. The identification of suspected colonies as belonging to the genus *Legionella* can be accomplished by demonstrating L-cysteine requirement and/or performing

Fig. 18.28 **A**, *Legionella pneumophila* (arrow) in a specimen smear stained using the direct fluorescent antibody (DFA) technique ($\times 450$). **B**, *Legionella pneumophila* (arrow) in a specimen smear stained using the immunofluorescence technique ($\times 1000$). Note the intense peripheral staining of the organisms.

MALDI-TOF mass spectrometry. An FDA-approved immunofluorescent antibody test (Fig. 18.28) for all *L. pneumophila* serogroups is also available. Further biochemical testing has limited value, and identification of isolates to the species level is usually not necessary. MALDI-TOF mass spectrometry is dependent on libraries in the FDA-approved and/or research use only databases, and this method is frequently successful. Definitive identification of less common species is usually performed at reference or public health laboratories, frequently using 16S ribosomal ribonucleic acid (rRNA) or next-generation sequencing methodology.

Rapid methods

Urine antigen test

The FDA has approved several microplate enzyme immunoassay and rapid immunochromatographic assays for *Legionella* antigen detection in urine specimens. The rapid immunochromatographic assays detect soluble antigen from *L. pneumophila* serogroup 1. Tests generally have reported sensitivities and specificities of 95% or higher. Antigens can be detected by day 3 of the infection and can persist for 1 year; consequently, the test is of limited value in persons with a recent history of *Legionella* infection.

Enzyme immunoassays are used by many clinical laboratories. Compared with culture, when using concentrated urine, the sensitivity of enzyme immunoassays ranges from 90% to 94%, and the specificity ranges from 97% to 100%. Because *Legionella* species other than *L. pneumophila* serogroup 1 cause infections, it is important to confirm results with culture. In addition to persistent antigenuria following clinical disease, as mentioned earlier, prolonged secretion has been associated with immunosuppression, renal failure, and chronic alcoholism. Conversely, early antimicrobial intervention with macrolides may decrease antigen excretion in some patients. Despite some limitations, these rapid tests represent an important step forward in timely diagnosis of *Legionella* infections.

Serologic testing

The indirect fluorescent antibody (IFA) assay is the most common method employed for serologic diagnosis of legionellosis, although other methods, such as enzyme-linked immunosorbent assay, are available. For IFA, heat-killed or formalin-killed

bacteria are fixed to a microscope slide. Higher antibody titers can be seen with heat-treated organisms; however, less cross-reactivity occurs with formalin preparations. Cross-reacting immunoglobulins have been reported in patients with an infection caused by gram-negative bacilli, *Mycoplasma*, or *Chlamydia*. Only about 50% of patients with Legionnaires' disease seroconvert within 2 weeks. The sensitivity of serologic tests is reported to be 75% to 80%, with a specificity of 90% to 100%.

Because some patients develop IgM-only, IgG-only, or IgA-only responses, and IgM levels can persist for months, it is best to measure total antibody in acute and convalescent serum. A fourfold rise in titer to a titer of at least 1 : 128 is the most accurate method to diagnose infection by serologic testing. Serology is most useful for epidemiologic purposes because of its retrospective nature.

Antimicrobial susceptibility

Susceptibility testing of *Legionella* spp. is not standardized or routinely performed. When infections are diagnosed early, they can usually be treated successfully with a macrolide, ketolide, or doxycycline. Early diagnosis and treatment are particularly important in healthcare-associated infections because they usually involve immunocompromised patients, and the disease often takes an aggressive course.

Bordetella

Both *Bordetella pertussis* and *Bordetella parapertussis* are primary human pathogens of the respiratory tract, causing **whooping cough** or **pertussis**, although the latter organism is usually associated with a milder form of the disease. At least 12 other species are recognized, and about 11 in total have been found in humans. *Bordetella bronchiseptica* and *Bordetella avium* are respiratory tract pathogens of wild and domestic birds and mammals and are generally nonfastidious and recoverable on routine microbiological culture media. *B. bronchiseptica* is an opportunistic human pathogen, causing respiratory and wound infections. *Bordetella holmesii* and *Bordetella trematum* are more recently described species and are agents of immunocompromised bacteremia (*B. holmesii*) and wound or ear infection (*B. trematum*). *Bordetella ansorpii* has been reported as a rare cause of septicemia.

General characteristics

Members of the genus *Bordetella* are small, gram-negative bacilli or coccobacilli. All are obligate aerobic bacteria, grow best at 35° to 37° C, do not ferment carbohydrates, oxidize amino acids, are relatively inactive in biochemical test systems, and produce catalase, although this is variable in *B. pertussis*. *B. pertussis* is fastidious and requires special collection and transport systems and culture media. *B. pertussis* is inhibited by fatty acids, metal ions, sulfides, and peroxides, constituents found in many media. Media for the isolation of *B. pertussis* require protective substances, such as charcoal, blood, or starch, to bind and neutralize inhibitory substances. The other *Bordetella* spp., except for *B. parapertussis*, are less fastidious and grow on MAC agar or media containing blood.

Clinically significant species

Bordetella pertussis and *Bordetella parapertussis*

Virulence factors

B. pertussis possesses various virulence factors that play a role in the pathogenesis of disease. **Filamentous hemagglutinin** (FHA) and pertactin (a 69-kilodalton [kDa] outer membrane protein) are believed to facilitate attachment to ciliated epithelial cells. **Pertussis toxin** (PT) is a protein exotoxin that produces a wide variety of responses in vivo. The main activity of PT is modification of host proteins by adenosine diphosphate-ribosyl transferase, which interferes with signal transduction. *B. parapertussis* and *B. bronchiseptica* contain the structural gene for PT but do not express the complete operon. *B. pertussis* also produces adenylate cyclase toxin, which inhibits host epithelial and immune effector cells by inducing supraphysiologic concentrations of cyclic adenosine monophosphate. **Tracheal cytotoxin** contributes to pathogenesis by causing ciliostasis, inhibiting DNA synthesis, and promoting cell death. Other virulence factors have been proposed, but their roles in disease are unclear.

Clinical manifestations

Classic pertussis resulting from *B. pertussis* infection occurs after exposure to the organism through the respiratory tract. There is a 1- to 3-week incubation period, usually 7 to 10 days. The symptoms of the initial **catarrhal phase** are insidious and nonspecific and include sneezing, mild cough, runny nose, and perhaps conjunctivitis. At this stage, the infection is highly communicable because of the large number of organisms in the upper respiratory tract. However, cultures are not often performed at this stage because the symptoms are nonspecific.

The **paroxysmal phase** follows the catarrhal phase. The hallmark of this phase is the sudden onset of severe, repetitive coughing followed by the characteristic “whoop” at the end of the coughing spell. The whooping sound is caused by the rapid gasp for air following the prolonged bout of coughing. Coughing spells may occur many times a day and are sometimes followed by vomiting. Young children might experience apnea, pneumonia, or both and require aid in maintaining a patent airway. Many of these symptoms may be either absent or altered in very young infants, partially immunized children, or adolescents and adults. *B. parapertussis* generally causes a similar disease with milder symptoms. The **convalescent**

phase of disease generally begins within 4 weeks of onset with a decrease in frequency and severity of the coughing spells. Complete recovery may require weeks or months. Adults may or may not experience respiratory symptoms, which can range in severity from persistent cough to acute exacerbation of chronic bronchitis.

Epidemiology

Pertussis is a human disease; no animal reservoir or vector has been found. Infections caused by *Bordetella* spp. are acquired through the respiratory tract via respiratory aerosols or direct contact with infectious secretions. Organisms are uniquely adapted to adhere to and replicate on ciliated respiratory epithelial cells. The organisms remain localized to the respiratory tract, but toxins and other virulence factors that can have systemic effects are produced.

Pertussis is one of the most highly communicable diseases of childhood; secondary attack rates of 80% occur among susceptible contacts. Of all childhood diseases for which universal vaccination is recommended, only pertussis has an increased rate of incidence over the past decade. There were 18,617 cases of pertussis reported to the CDC in 2019. It is believed that many pertussis infections are not diagnosed; therefore cases are underreported. Infants younger than 1 year of age, who are too young to be fully vaccinated, continue to have the highest incidence of disease and are at greatest risk for severe disease. Adolescents and adults serve as reservoirs when their immunity from acellular pertussis (aP) vaccine, given in combination with the diphtheria and tetanus toxoids (DTaP), is either immature or waning.

The childhood vaccination series consists of five doses from 6 weeks to 6 years of age, and decreases in immunization rates lead to increased attack rates or major epidemics. Immunity is short lived, and *B. pertussis* appears to be maintained in the human population by adults who become transiently colonized. Single-dose booster vaccines, administered in combination with diphtheria and tetanus toxoids, are available for use in both adolescents and adults. If a child has recovered from confirmed pertussis, additional doses of pertussis vaccine are unnecessary.

Miscellaneous species

The remaining *Bordetella* spp. are opportunistic human pathogens. *B. bronchiseptica* is a respiratory tract pathogen of numerous animals, including dogs, in which it causes kennel cough. Symptomatic *B. bronchiseptica* infections in humans generally manifest with a nonspecific cough or bronchitis, and often patients have underlying conditions, such as immunosuppression or contact with animals. *B. bronchiseptica* and *B. holmesii* have been infrequently associated with pertussis syndrome and other respiratory tract infections.

Laboratory diagnosis

Contemporary laboratory diagnosis of pertussis generally employs culture isolation with or without PCR testing. DFA assays have low sensitivity and are not recommended. Other stains also have no role in diagnosis. Organisms do not survive well outside the host, so culture can also lack sensitivity.

Specimen collection and handling

Nasopharyngeal aspirates or swabs of Dacron polyester with a nonwire shaft constitute the specimen of choice for culture and PCR testing for *Bordetella*. Flocked swabs (FLOQSwab; Copan Diagnostics, Murrieta, CA) tend to have higher sensitivities when attempting to recover respiratory pathogens. Throat cultures have a much lower sensitivity and should be discouraged. Generally, two swabs are collected, one through each of the external nares; the swabs should be inserted as far back as possible into the nasopharynx, rotated, held a few seconds, and then gently withdrawn. In practice, swabs are used more commonly than aspiration methods.

Nasopharyngeal swab specimens should be plated directly onto culture media or transferred to an appropriate transport system at the bedside. Transport media, such as casamino acid (1% casein hydrolysate) or Amies with charcoal, can preserve viability up to 48 hours. Swabs for PCR can be transported dry at room temperature. Specimens for culture should be transported at room temperature and transferred to culture media as soon as they arrive at the laboratory.

Nucleic acid detection

Nucleic acid amplification methods can circumvent many of the problems associated with specimen transport and bacterial cultivation. Detection of *B. pertussis* DNA by PCR amplification has gained considerable use, but a lack of standardization and single target testing has also led to false-positive results and outbreaks mistakenly attributed to pertussis. Laboratories should use at least two DNA targets (e.g., *IS481* and *ptxP*) and may need to seek confirmation to avoid the mischaracterization of respiratory illness. Some PCR targets are not only found in *B. pertussis* but also in *B. parapertussis*, *B. holmesii*, and *B. bronchiseptica*. However, PCR assays are generally regarded as more sensitive than cultures and DFA assays. Some PCR kits including multiplex assays have received FDA approval.

Isolation and identification

Isolation methods

Since the original development of **Bordet-Gengou potato infusion agar** with glycerol and horse or sheep blood, few other formulations have been as successful. Alternative media include Regan-Lowe medium, which contains charcoal, starch, horse blood, cephalixin, and amphotericin B, and Stainer-Scholte medium, which contains casamino acids. Regan-Lowe medium is identical in composition to the transport medium of Regan and Lowe, except that it contains agar at full strength. The medium has a shelf life of 8 weeks and is commercially available. Care should be taken to ensure the appropriate concentration of cephalixin in the medium. Some strains of *B. pertussis* have been reported to be inhibited at 40 mg/L or greater. For this reason, it may be advisable to also plate a medium without cephalixin.

Plates for the recovery of *Bordetella* spp. should be incubated at 35°C in ambient air for a minimum of 7 days. It is important to ensure adequate moisture during this period to prevent plates from drying out. Small colonies of *B. pertussis*

Fig. 18.29 Five-day-old *Bordetella pertussis* colonies on charcoal-horse blood agar (incident light from lower-right corner).

are detected in 3 to 7 days, whereas *B. parapertussis* is detected between days 2 and 3. A stereomicroscope should be used to detect the colonies before they become visible to the unaided eye.

Colony morphology

On charcoal-horse blood and Regan-Lowe media, young colonies are smooth, glistening, and silver, resembling mercury droplets (Fig. 18.29). Colonies turn whitish gray as they age. On Bordet-Gengou agar, colonies of *B. pertussis* and *B. parapertussis* are hemolytic.

Identification methods

On Gram stain of culture isolates, the organisms appear as tiny gram-negative coccobacilli and may become elongated if recovered from media containing cephalixin. It may be necessary to increase the safranin counterstaining time to 2 minutes to see typical morphology. Because of the fastidious nature of these organisms, identification by biochemical testing is difficult. Growth patterns should be observed, and biochemical tests can be performed (Table 18.8) to confirm the identification. Box 18.2 summarizes the laboratory diagnosis of pertussis by culture. MALDI-TOF mass spectrometry and 16S rRNA gene sequencing provide accurate identification, depending on the databases used.

Serologic testing

Serologic diagnosis of pertussis can be used to study outbreaks and to document seroconversion after immunization or infection. In addition, serologic testing can identify more cases in older vaccinated children, adolescents, and adults. However, assays cannot distinguish an immune response between vaccination or infection. In addition, serology cannot identify *B. parapertussis* infection. Detecting antipertussis toxin antibody by enzyme immunoassay or bead-based assays is recommended for diagnosing exposure to *B. pertussis*. Demonstrating a fourfold rise in titer in paired sera is

Table 18.8 Differential characteristics of *Bordetella* species infecting humans

Characteristics	<i>B. pertussis</i>	<i>B. parapertussis</i>	<i>B. bronchiseptica</i>
Growth on			
Charcoal–horse blood	+ (3–5 days)	+ (2–3 days)	+ (1–2 days)
Blood agar	–	+	+
MacConkey agar	–	–	+
Catalase	+	+	+
Oxidase	+	–	+
Urease production	–	+ (24 hours)	+ (4 hours)
Nitrate reduction	–	–	+
Motility	–	–	+

BOX 18.2 Summary of laboratory diagnosis of pertussis by culture

- Using Dacron swabs or flocked swabs, collect two nasopharyngeal specimens.
- Transfer to transport system:
 - Casamino acid (1% casein hydrolysate)
 - Amies transport medium with charcoal
 - Regan-Lowe transport medium
- Perform polymerase chain reaction (PCR) test for *Bordetella pertussis*.
- Inoculate Bordet-Gengou, Regan-Lowe, or Stainer-Scholte medium. Incubate medium in a moist chamber (without carbon dioxide [CO₂]) at 35° C for 7 days.
- Examine plates using a stereomicroscope for typical colonies.
- Screen *B. pertussis*/*B. parapertussis*-like colonies with Gram stain, and use matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry or 16S rRNA gene sequencing to confirm.

optimal for diagnosis. A single IgG antibody titer greater than 100 IU/mL is indicative of recent infection, whereas a titer less than 40 IU/mL is not. Assays are in need of better standardization. Detecting IgM is not recommended.

Antimicrobial susceptibility

B. pertussis and *B. parapertussis* are generally sensitive to the macrolides, ketolides, penicillins, and tetracyclines but are resistant to oral cephalosporins. Although a few strains of erythromycin-resistant *B. pertussis* have been reported, erythromycin, a macrolide, is still recommended for pertussis treatment and prophylaxis. Erythromycin is important for eradication of the organism and prevention of secondary cases, but it has clinical efficacy only if treatment is started during the catarrhal phase of disease. Azithromycin has fewer and milder side effects, has a longer half-life, and requires fewer daily doses, resulting in better patient compliance. Trimethoprim-sulfamethoxazole is also an alternative for treatment or prophylaxis. Routine antimicrobial susceptibility testing of *B. pertussis* or *B. parapertussis* is unnecessary because of predictable sensitivity to the macrolides. The susceptibility of *B. bronchiseptica* is unpredictable, and tests should be performed, although the organism is usually susceptible to the aminoglycosides.

POINTS TO REMEMBER

- The genus *Haemophilus* consists of gram-negative coccobacilli or bacilli. They are facultative anaerobes that are generally oxidase and catalase positive.
- *Haemophilus* spp. require preformed growth factors (X and V factors) present in blood. Testing for these factors with X and V strips and the porphyrin test are important aspects of laboratory identification procedures.
- The advent of the Hib vaccine has decreased infection by *H. influenzae* type b in children in the United States by 99%, but serotype b remains prevalent in developing countries.
- *H. ducreyi* causes the STD chancroid. In contrast with many other *Haemophilus* spp., it is not considered part of the normal oral biota of humans.
- HACEK is an acronym for *Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* spp. The HACEK group is an important cause of endocarditis, specifically related to poor oral hygiene or dental procedures.
- *Pasteurella*, *Brucella*, and *Francisella* spp. are important causes of zoonotic infections.
- The most common *Pasteurella* species isolated from humans, *P. multocida*, most frequently causes wound infections after cat or dog bites.
- *Brucella* and *Francisella* spp. are fastidious gram-negative coccobacilli causing zoonoses and are considered potential bioterrorism agents.
- *Legionella* spp. are pleomorphic, weakly staining gram-negative bacilli. They are transmitted to humans primarily via aerosolized particles. Sources include contaminated potable water distribution systems, respiratory therapy equipment, and recreational waters. Transmission among humans has not been demonstrated.
- Legionnaires' disease is a febrile illness with pneumonia that is often associated with travel. Pontiac fever is a milder febrile disease resembling influenza that may be caused by inhalation of bacterial toxin.
- On BCYE α agar, *L. pneumophila* colonies appear convex and glistening. The central portion of young colonies have a "ground-glass" appearance (light gray and granular), whereas the periphery of the colony has pink, light blue, or bottle-green bands.
- Using a combination of nonselective and selective BCYE α agar is the best strategy for isolation of *Legionella* organisms. Acid treatment of specimens contaminated with other bacteria before inoculation enhances isolation of *Legionella* spp.
- A rapid assay useful for the detection of *Legionella pneumophila* serogroup 1 is the urine antigen test.
- *B. pertussis* and *B. parapertussis* cause pertussis, or whooping cough, and are primary human pathogens of the respiratory tract. They are acquired through the respiratory tract via respiratory aerosols or direct contact with infectious secretions.
- *Bordetella* spp. are tiny, gram-negative coccobacilli and might become elongated if recovered from media containing cephalixin.
- For the detection of *Bordetella* spp., nasopharyngeal aspirates or swab specimens should be plated directly onto culture media or transferred to an appropriate transport system (casamino acid or Amies transport medium) at the bedside.
- Contemporary laboratory diagnosis of pertussis generally employs culture isolation with or without PCR testing.

- *B. bronchiseptica* can be part of the normal oral biota of dogs and cats, and infections in humans typically follow bites by these animals.
- Antimicrobial susceptibility testing is not normally performed on *B. pertussis*. The drug of choice in the treatment of pertussis is erythromycin.

LEARNING ASSESSMENT QUESTIONS

- What are the growth patterns of *Haemophilus influenzae* with the X and V strip test?
- A microbiologist is reading a sputum culture and notices tiny, translucent colonies growing closely around a β -hemolytic colony on sheep blood agar (SBA). The colonies are growing in the area where the blood has been hemolyzed. What is the probable identity of the organism that is growing closely to the β -hemolytic organism?
 - Neisseria* spp.
 - Haemophilus* spp.
 - Acinetobacter* spp.
 - Moraxella* spp.
- Which bacterium is the causative agent of kennel cough in dogs and is occasionally associated with respiratory tract infections in humans?
 - Bordetella bronchiseptica*
 - Pasteurella multocida*
 - Francisella tularensis*
 - Capnocytophaga canimorsus*
- What are the optimal growth conditions for the recovery of *Haemophilus ducreyi*?
- How would you compare the pathogenesis of *Haemophilus aegyptius* with *Haemophilus influenzae* biogroup *aegyptius*?
- A cervical culture for possible gonococcal infection is sent to the microbiology laboratory. After 24 hours of incubation, the modified Thayer-Martin plate has small opaque colonies that adhere slightly to the medium. Microscopic examination reveals gram-negative coccobacilli, many with square ends. The organism ferments glucose and is superoxol and catalase negative. What is the most likely identification of the organism?
 - Neisseria gonorrhoeae*
 - Kingella denitrificans*
 - Moraxella catarrhalis*
 - Haemophilus ducreyi*
- A 52-year-old male patient who had recently received a kidney transplant was admitted to the hospital with a low-grade fever, a heart murmur, and neutropenia. He had a history of periodontal disease and recently had had two teeth extracted. Blood cultures were positive after 48 hours. The isolate grew on chocolate agar and SBA in 5% CO₂. The colonies were nonhemolytic, slightly adhered to the surface of the media, and had a slight yellow appearance when removed. The isolate was catalase, indole, and oxidase negative. Microscopic morphology indicated gram-negative fusiform bacilli. What is the most probable identification of this organism?
 - Aggregatibacter aphrophilus*
 - Kingella kingae*
 - Cardiobacterium hominis*
 - Capnocytophaga* spp.
- An isolate from an infected cat bite is oxidase, catalase, ornithine decarboxylase, indole, and urease negative. After 48 hours of incubation at 35° C, growth on SBA was described as mucoid colonies exhibiting a greenish-brown halo. A McConkey agar plate showed no growth. Which organism is the mostly likely cause of the infection?
 - Pasteurella multocida*
 - Bordetella bronchiseptica*
 - Francisella tularensis*
 - Capnocytophaga canimorsus*
- Which microbiologic tests are most useful in differentiating *Brucella melitensis* from *Haemophilus influenzae*?
- A patient is complaining of a painful cervical lymph node following a case of pharyngitis. Further investigation reveals that the patient consumed a medium-cooked wild rabbit in a restaurant in Germany 2 months earlier. What is the most likely cause of the infection?
- Which risk factors contribute to the more severe form of legionellosis?
- Which environmental factors contribute to infection caused by *Legionella* spp.?
- What is the culture medium of choice for the recovery of *Legionella* spp.?
- Which factors of *Legionella* can contribute to the colonization of human-made water supplies?
- What is the best nonrespiratory specimen for rapid detection of *Legionella*?
- Which presumptive identification methods are currently used to identify *Legionella* spp. in culture?
- Besides respiratory tract specimens, which clinical specimen is useful for the sensitive detection of *Legionella* antigen?
 - Blood
 - Stool
 - Urine
 - Cerebrospinal fluid (CSF)
- Are adults immune to *Bordetella pertussis* infection? Explain your answer.
- What are the clinical samples of choice for the diagnosis of *Bordetella pertussis* infection?
- Which transport media are appropriate for maximum recovery of *Bordetella pertussis*?
- Which method is preferred for the rapid detection of *Bordetella* in nasopharyngeal specimens?
- How would you compare the diseases caused by *Bordetella pertussis* and *B. parapertussis*?
- Is serology a good method to identify and respond to pertussis outbreaks in real time?
- What is the antimicrobial agent of choice for the treatment of pertussis?
 - Ampicillin
 - Amoxicillin
 - Erythromycin
 - Penicillin
- Bordetella bronchiseptica* is considered normal oral biota in which of the following?
 - Humans
 - Dogs
 - Cows
 - Rats

OBJECTIVES

After reading and studying this chapter, you should be able to:

1. Describe the general characteristics of organisms that belong to the order Enterobacterales.
2. Describe the antigenic structures of the order Enterobacterales.
3. Explain how antigenic structures are used for identification of clinically significant Enterobacterales.
4. Compare the virulence factors of the *Escherichia coli* strains pathogenic for the gastrointestinal tract and the *E. coli* strains involved in extraintestinal human diseases.
5. Compare the pathogenesis of the three species of *Yersinia* most often recovered from humans.
6. Describe the pathogenesis of the clinically relevant members of the order Enterobacterales.
7. Given an organism's characteristic growth on nonselective and selective differential media, presumptively identify the isolate to the genus level.
8. Match the species of *Shigella* to their appropriate serogroup.
9. Given the key reactions for identification, place an unknown organism in its proper family, genus, and species.
10. Develop an algorithm for the identification of the clinically significant Enterobacterales.

KEY TERMS

Bacillary dysentery

Buboes

Diffusely adherent *Escherichia coli* (DAEC)

Enteric

Enteraggregative *Escherichia coli* (EAEC)

Enterohemorrhagic *Escherichia coli* (EHEC)

Enteroinvasive *Escherichia coli* (EIEC)

Enteropathogenic <i>Escherichia coli</i> (EPEC)	Shiga toxin (Stx)
Enterotoxigenic <i>Escherichia coli</i> (ETEC)	Shiga toxin–producing <i>Escherichia coli</i> (STEC)
H antigen	Typhoid fever
K antigen	Traveler's diarrhea
O antigen	Verotoxin
	Vi antigen

Case in point

A 71-year-old male patient who was hospitalized for diabetic ketoacidosis complained of flank pain and painful urination. A urine sample was plated, and after 18 hours of incubation, a MacConkey (MAC) agar plate showed moderate growth of lactose-fermenting organisms. A sheep blood agar (SBA) plate revealed oxidase-negative, nonhemolytic colonies. The following biochemical results were obtained on the isolate: H₂S negative, indole, methyl red, Voges-Proskauer, citrate (IMViC) reactions were + + – +; urea was hydrolyzed; and arginine and ornithine were decarboxylated. Antimicrobial susceptibility test revealed resistance to cefotaxime, norfloxacin, ciprofloxacin, and the aminoglycosides.

Issues to consider

After reading the patient's case history, consider:

- The significance of this patient's health status and medical history
- The colony morphology feature that provides clues about the identity of the organism
- The biochemical tests that are the most specific for identification of this organism

Comprehensive genomic analysis with phylogenetic reconstructions of members of the heterogeneous family Enterobacteriaceae resulted in the creation of a new order, Enterobacterales. All members of the original family Enterobacteriaceae were placed in the new order. The order Enterobacterales was divided into nine families: Bruguierivoraceae, Budviciaceae, Enterobacteriaceae, Erwiniaceae, Hafniaceae, Morganellaceae, Pectobacteriaceae, Thorselliaceae, and Yersiniaceae. Genera remaining within the family Enterobacteriaceae include *Citrobacter*, *Cronobacter*, *Enterobacter*, *Escherichia*, *Klebsiella*, *Kluyvera*, *Raoultella*, *Salmonella*, *Shigella*, and several others. Despite the enormity and diversity of this order, clinical isolates in acute-care facilities consist primarily of only a few species. However, it is important to be aware of other species that cause significant human infectious diseases.

This chapter is divided into three major areas: (1) clinically significant species that cause opportunistic infections, (2) primary intestinal pathogens and their related human infections, and (3) methods of identification of these organisms. Among the many organisms in the order Enterobacterales, this chapter focuses only on the members that have been associated with human diseases.

General characteristics

The order Enterobacterales consists of numerous diverse organisms. They have several key laboratory features in common, but as 16S rRNA and deoxyribonucleic acid (DNA) studies on

these bacteria progress, classification of the members changes. Some organisms are added (e.g., *Enterobacter bugandensis*), new species are being discovered, and some may be removed from the order. Currently, several key characteristics help place an organism in the order Enterobacterales (Box 19.1).

Microscopic and colony morphology

Members of the order Enterobacterales are gram-negative, non-spore-forming, facultatively anaerobic bacilli. On Gram-stained smears, they can appear as coccobacilli or as straight rods. Colony morphology on nonselective media, such as SBA or chocolate (CHOC) agar, is of little value in initial identification. Except for certain members that produce characteristically large and very mucoid colonies (e.g., *Klebsiella* and sometimes *Enterobacter*), members of this order produce large, moist, gray colonies on nonselective media and are indistinguishable. However, many isolates of *E. coli* are β -hemolytic.

A wide variety of selective and differential media, such as eosin-methylene blue (EMB) and MAC agars, and highly selective media, such as Hektoen enteric (HE) and xylose-lysine-desoxycholate (XLD) agars, are available for presumptive identification of clinical pathogens. These media contain one or more carbohydrates, such as lactose and sucrose, which show the ability of the species to ferment specific carbohydrates. Acid production via fermentation is indicated by a color change on the medium, which results from a decrease in pH detected by a pH indicator present in the medium. Nonfermenting species are differentiated by lack of color change, with colonies retaining the original color of the medium. Species that produce hydrogen sulfide (H₂S) can be readily distinguished when placed on HE or XLD agar. HE and XLD agars contain sodium thiosulfate and ferric ammonium citrate, which produce blackening of H₂S-producing colonies. These features have been used to initially differentiate and characterize certain genera. Definitive identification depends on biochemical reactions, antigen determination, and, more recently, protein profiles via matrix-assisted laser desorption/ionization–time-of-flight (MALDI-TOF) mass spectrometry.

Classification

The order Enterobacterales belongs to the class Gammaproteobacteria. It includes over 60 genera and 250 species. Most of the species are placed into the family Enterobacteriaceae.

BOX 19.1 Key characteristics of the order Enterobacterales

- They are gram-negative, facultatively anaerobic, non-spore-forming bacilli and coccobacilli.
- They do not produce cytochrome oxidase, except *Plesiomonas*.
- They ferment glucose.
- They reduce nitrate to nitrite, except *Photobacterium* and *Xenorhabdus*.
- They are motile at 37°C, except *Klebsiella*, *Shigella*, and *Yersinia*.
- Except for *Klebsiella*, *Proteus*, and some *Enterobacter* isolates, none has remarkable colony morphology on laboratory media. They appear large, moist, and gray on sheep blood agar (SBA), chocolate agar, and most nonselective media. Most are nonhemolytic on SBA, except *E. coli*.

Table 19.1 lists bacterial species in the order Enterobacterales and their respective families. Table 19.2 shows the biochemical features of select genera. Although taxonomists use nucleic acid sequences, biochemical features are an easy and effective way of classifying bacteria into genera and is employed throughout this chapter.

Virulence and antigenic factors

Many factors affect the virulence of the Enterobacterales, such as the ability to adhere, colonize, produce toxins, and evade host defenses. Many pathogenic species of this order possess antigens that can be used in the identification of different serologic groups. These antigens include:

- **O antigen**, or somatic antigen: a heat-stable antigen located on the cell wall
- **H antigen**, or flagellar antigen: a heat-labile antigen found on the surface of flagella, the structures responsible for motility
- **K antigen**, or capsular antigen: a heat-labile polysaccharide found only in certain encapsulated species. Examples are the K1 antigen of *E. coli* and the **Vi antigen** of *Salmonella enterica* subsp. *enterica* serotype Typhi.

Clinical significance

Members of the order Enterobacterales are ubiquitous in nature. Some species exist as free-living organisms in water, soil, or sewage, and some are animal or plant pathogens. The medically important Enterobacterales, with few exceptions, share a common niche; they reside in the gastrointestinal (GI) tract and are commonly referred to as **enteric** bacilli. Except for *Salmonella*, *Shigella*, and *Yersinia*, they can be resident microbiota if confined to their natural environment.

Based on the clinical infections produced, members of the order Enterobacterales can be divided into two broad categories: (1) opportunistic pathogens and (2) primary pathogens. The opportunistic pathogens are often a part of the usual intestinal microbiota of both humans and animals. However, outside their normal body sites, these organisms can produce serious extraintestinal, opportunistic infections. For example, *E. coli*, one of the best-studied members of the family Enterobacteriaceae, is a member of the normal bowel biota but can cause urinary tract infections (UTIs), septicemia, wound infections in healthy individuals, and meningitis in neonates.

Other organisms can be equally devastating in immunocompromised hosts or when introduced to wounds from contaminated soil or water. *S. enterica*, *Shigella* spp., and *Yersinia* spp. are considered primary or true pathogens; that is, they are not present as commensal biota in the GI tract of humans. These organisms produce infections resulting from ingestion of contaminated food or water or from other sources. Table 19.3 lists some diseases associated with members of the order Enterobacterales.

Antimicrobial resistance in the Enterobacterales

In 2019, the Centers for Disease Control and Prevention (CDC) listed 18 drug-resistant threats to the United States categorized based on level of concern: urgent, serious, and

Table 19.1 Classification of selected species within the order Enterobacterales

Family	Genus	Species
Enterobacteriaceae	<i>Escherichia</i>	<i>coli</i>
		<i>albertii</i>
		<i>fergusonii</i>
		<i>dysenteriae</i>
		<i>flexneri</i>
	<i>Shigella</i>	<i>boydii</i>
		<i>sonnei</i>
		<i>freundii</i> complex
	<i>Citrobacter</i>	<i>koseri</i>
		<i>amalonaticus</i>
		<i>sakazakii</i>
	<i>Cronobacter</i>	<i>malonaticus</i>
		<i>farmeri</i>
	<i>Enterobacter</i>	<i>cloacae</i> complex
		<i>Klebsiella pneumoniae</i> subsp. <i>pneumoniae</i>
	<i>Klebsiella</i>	<i>pneumoniae</i> subsp. <i>ozaenae</i>
		<i>pneumoniae</i> subsp. <i>rhinoscleromatis</i>
		<i>aerogenes</i>
		<i>variicola</i>
		<i>Raoultella ornitholytica</i>
		<i>Salmonella enterica bongori</i>
		<i>Cronobacter sakazakii malonaticus</i>
Hafniaceae	<i>Edwardsiella</i>	<i>tarda</i>
		<i>hoshinae</i>
Morganellaceae	<i>Hafnia</i>	<i>alvei</i>
		<i>paralvei</i>
	<i>Morganella</i>	<i>morganii</i>
		<i>Proteus mirabilis</i>

Table 19.3 Bacterial species and infections they commonly produce

Bacterial species	Diseases
<i>Citrobacter</i> spp.	Urinary tract
<i>Cronobacter</i> spp.	Opportunistic and healthcare-associated infections, wound infections, bacteremia, meningitis
<i>Edwardsiella</i> spp.	Diarrhea, wound infections, septicemia, meningitis, enteric fever
<i>Enterobacter</i> spp.	Opportunistic and healthcare-associated infections, wound infections, septicemia, bacteriuria
<i>Escherichia coli</i>	Bacteriuria, septicemia, neonatal sepsis, meningitis, diarrheal syndrome
<i>Hafnia alvei</i>	Diarrhea, bacteremia, respiratory tract infections
<i>Klebsiella</i> spp.	Opportunistic and healthcare-associated infections, bacteriuria, pneumonia, septicemia
<i>Morganella</i> spp.	Opportunistic and healthcare-associated infections
<i>Pantoeae</i>	Opportunistic and healthcare-associated infections
<i>Proteus</i> spp.	Bacteriuria, wound infections, septicemia
<i>Providencia</i> spp.	Opportunistic and healthcare-associated infections, wound infections, septicemia, bacteriuria
<i>Raoultella ornithinolytica</i>	Opportunistic and healthcare-associated infections, wound infections, septicemia, bacteriuria
<i>Salmonella</i> spp.	Septicemia, enteric fever, diarrhea
<i>Shigella</i> spp.	Diarrhea, dysentery
<i>Serratia</i> spp.	Opportunistic and healthcare-associated infections, wound infections, septicemia, bacteriuria
<i>Yersinia pestis</i>	Plague
<i>Yersinia pseudotuberculosis</i>	Mesenteric adenitis, diarrhea
<i>Yersinia enterocolitica</i>	Mesenteric adenitis, diarrhea

concerning. Carbapenem-resistant Enterobacteriaceae (CRE; referring to the original family Enterobacteriaceae) was listed as one of five urgent concerns. Infections with CREs, particularly in health care settings, are often life-threatening. CRE is defined as resistance to imipenem, meropenem, doripenem, or

ertapenem, or documentation that the isolate possesses a carbapenemase. The Xpert Carba-R Assay (Cepheid, Sunnyvale, CA) is a real-time multiplex polymerase chain reaction (PCR) assay that rapidly detects five genes coding for carbapenemases. The assay has a sensitivity of 100% and a specificity of

>99%. Screening of hospitalized patients is recommended by many public health organizations to help contain the spread of carbapenemase-producing bacteria.

With the discovery of the plasmid-transmissible colistin marker *mcr-1* in a CRE strain in 2016, antimicrobial resistance in Enterobacterales continues to grow more serious. For example, an increasing number of *E. coli*, *K. pneumoniae*, and *Klebsiella oxytoca* clinical strains produce plasmid-mediated extended-spectrum β -lactamases (ESBLs) including carbapenemases, cephalosporinases, or metallo- β -lactamases, which can inactivate extended-spectrum cephalosporins. The *K. pneumoniae* carbapenemase (KPC), found in *Klebsiella* spp., *Enterobacter* spp., and *Serratia marcescens*, now joins VIM, IMP, New Delhi metallo- β -lactamase (NDM-1), and others in the growing arsenal of resistance genes found in CREs. For definitions and more information on antimicrobial classes, see [Chapter 12](#).

Opportunistic members of the order Enterobacterales and associated infections

Escherichia coli

E. coli, the most significant species in the genus *Escherichia*, was first described by Escherich in 1885. *E. coli* was initially considered a harmless member of the colon resident biota. It

is now recognized as an important human pathogen associated with a wide range of clinical syndromes, including UTIs, diarrheal diseases, and central nervous system infections. It is so commonly isolated from colon biota that *E. coli* is used as a primary marker of fecal contamination in water quality testing.

Most strains of *E. coli* are motile and generally possess adhesive fimbriae and sex pili, and O, H, and K antigens. *E. coli* O groups have shown remarkable cross-reactivity with O antigens from other members of the Enterobacteriaceae, most notably *Shigella* spp. This is one of the reasons *Escherichia* and *Shigella* spp. are grouped together in the family Enterobacteriaceae. Serotyping for both O and H antigens is often useful in strain identification, particularly strains associated with serious enteric disease. The K antigen often masks the O antigen during bacterial agglutination testing with specific antiserum. This phenomenon can make it difficult to determine the serotype.

On certain selective and differential media, such as MAC or EMB agars, *E. coli* has a distinctive morphology. It usually appears as a lactose-positive (pink) colony with a surrounding area of precipitated bile salts on MAC agar ([Fig. 19.1](#)). On EMB agar, it has a green metallic sheen. *E. coli* typically has the following properties:

- Fermentation of glucose, lactose, trehalose, and xylose
- Production of indole from tryptophan
- Glucose fermentation by the mixed acid pathway: methyl red positive and Voges-Proskauer negative

Fig. 19.1 A, Typical dry, lactose-positive *Escherichia coli* growing on MacConkey (MAC) agar. Note the pink precipitate surrounding the individual colonies. B, Mucoid colonies of *E. coli* growing on MAC agar. C, Nonlactose-fermenting *E. coli* compared with typical lactose-fermenting *E. coli* on MAC agar. (B and C, Courtesy Jean Barnishan.)

- Does not produce H_2S , deoxyribonuclease (DNase), urease, or phenylalanine deaminase
- Cannot use citrate as a sole carbon source

Extraintestinal *Escherichia coli* infections

E. coli is one of the most common causes of septicemia and meningitis among neonates, accounting for about 40% of the cases of early-onset meningitis. Similar infections resulting from this organism are uncommon in older children. A newborn usually acquires the infection in the birth canal just before or during delivery, when the mother's vagina is heavily colonized. Infection may also result if contamination of the amniotic fluid occurs.

The strains associated with diarrheal disease appear to be distinct from strains associated with neonatal sepsis or meningitis. The capsular antigen K1, present in some strains of *E. coli*, is the most documented virulence factor associated with neonatal meningitis and septicemia infections. It is present on about 85% of isolates from these neonatal infections. The *E. coli* K1 capsule is immunochemically identical to the capsular antigen of *N. meningitidis* group B. Fatality rates for infants with meningitis caused by *E. coli* K1 are higher than the fatality rates for infants infected with non-K1 strains. In addition to the neonatal population, *E. coli* remains a clinically significant isolate in blood cultures from adults. *E. coli* bacteremia in adults may result from a urogenital tract infection or from a GI source.

Uropathogenic *Escherichia coli*

E. coli is widely recognized as the most common cause of UTIs in humans. The *E. coli* strains that cause UTIs usually originate in the large intestine as resident biota and can exist either as the predominant *E. coli* population or as a small part of the *E. coli* strains in the large intestine. Strains causing lower UTIs and acute pyelonephritis in immunocompetent hosts are different from strains causing disease in the urinary tracts of individuals who are compromised either by urinary tract defects or by instrumentation such as placement of catheters. *E. coli* strains that cause acute pyelonephritis in immunocompetent hosts have been shown to be the dominant resident *E. coli* in the colon. They belong to a few serotypes and are resistant to the antibacterial activity of human serum. Conversely, isolates from immunocompromised hosts consist of a wide variety of strains.

Strains that cause UTIs produce factors that allow them to attach to the urinary epithelial mucosa. The primary virulence factor associated with the ability of *E. coli* to cause UTIs is the production of pili, which allow uropathogenic strains to adhere to epithelial cells and not be washed out with urine flow. For example, about 80% of *E. coli* isolates causing acute pyelonephritis express pyelonephritis-associated pili encoded by the *papA* and *papG* genes. Other factors contributing to the virulence of uropathogenic *E. coli* include flagella, cytolysins, and aerobactin. Flagella facilitate bacterial dissemination. Cytolysins, also often characterized as hemolysins, can kill immune effector cells and inhibit phagocytosis and chemotaxis of certain white blood cells. Aerobactin allows the bacterial cell to chelate iron; free iron is generally unavailable within the host for use by bacteria.

Gastrointestinal *Escherichia coli* infections

E. coli produces several different GI syndromes and causes an estimated 10% of all case of foodborne, bacterial, acute gastroenteritis in the United States. Based on virulence factors, clinical manifestation, epidemiology, and different O and H serotypes, there are five major categories, or pathotypes, of diarrheagenic *E. coli*: **enterotoxigenic *Escherichia coli* (ETEC)**, **enteroinvasive *Escherichia coli* (EIEC)**, **enteropathogenic *Escherichia coli* (EPEC)**, **Shiga toxin-producing *Escherichia coli* (STEC)**, and **enteroaggregative *Escherichia coli* (EAEC)**. These five categories are sometimes collectively referred to as enterovirulent *E. coli* or diarrheagenic *E. coli*. The serotypes associated with these categories and the features associated with the intestinal infections produced by these strains are summarized in Table 19.4. It is often difficult to distinguish among *E. coli* strains that are part of the normal microbiota and the diarrheagenic strains by culture.

Enterotoxigenic *Escherichia coli*

ETEC strains are associated with diarrhea in adults and especially children living in tropical and subtropical climates, particularly in developing countries, where it is one of the major causes of infant bacterial diarrhea. In the United States and other Western industrialized nations, ETEC diarrhea is the most common cause of diarrheal disease in travelers, sometimes referred to as **traveler's diarrhea**. Travelers from industrialized countries often become infected with ETEC when visiting developing nations. ETEC infection is spread commonly via consumption of contaminated food or water. Poor hygiene, reduced availability of potable water, and inadequate sanitation are major contributing factors in the spread and transmission of this disease. A high infective dose (10^6 to 10^{10} organisms) is necessary to initiate disease in an immunocompetent individual. Protective mechanisms such as stomach acidity have been noted as inhibiting colonization and initiation of disease; *achlorhydria*, deficiency of hydrochloric acid within the stomach, seems to be a high-risk factor.

Colonization of ETEC in the proximal small intestine is mediated by greater than 20 fimbriae and nonfimbrial adhesion factors that permit ETEC to bind to specific receptors on the intestinal microvilli. Once ETEC strains are established, they can release one or both of two toxins: heat-labile toxin (LT) or heat-stable toxin (ST). The LT is similar in action and amino acid sequence to cholera toxin from *Vibrio cholerae*. LT consists of two fragments (A and B) that follow the A/B model of bacterial toxins in which A is the enzymatically active portion. The B moiety, or binding portion, confers the specificity. The B portion binds to the GM_1 ganglioside of the intestinal mucosa, providing entry for the A portion.

The A portion activates cellular adenylate cyclase, causing an increase in the conversion of adenosine triphosphate to cyclic adenosine monophosphate (cAMP). The consequence of cAMP accumulation is hypersecretion of electrolytes and fluids into the intestinal lumen, resulting in watery diarrhea similar to cholera. In contrast, ST stimulates guanylate cyclase, causing increased production of cyclic guanosine monophosphate, accumulation of which also causes hypersecretion.

The usually mild, self-limiting disease caused by ETEC is characterized by watery diarrhea, abdominal cramps, and sometimes nausea, usually with no vomiting or fever.

Table 19.4 Features of pathogenic *Escherichia coli*

Type	Virulence factors	Relevant disease	Relevant serotypes	Laboratory tests
Uropathogenic <i>E. coli</i>				
UPEC	P pilus/ <i>pap</i> pili, type 1 fimbriae	UTIs		
DAEC ^a	Afa/Dr adhesions	UTIs		
Enteric pathogens				
EPEC	Type IV bundle-forming pilus, type III secretion of Tir	Infantile diarrhea	O55:NM O55:H6 O111:NM O111:H2 O114:NM O114:H2	HeLa cell adherence assay, DNA probes
EHEC	Shiga toxins/verotoxin	Hemorrhagic diarrhea, colitis, HUS	O157:H7 O157:NM O26:H11 O104:H21 O111:H2 O111:H8 O113:H21 O118:H2	SMAC plates, MUG
EIEC	Invasion plasmid antigen	Dysentery	O124:H30 O143:NM O164:NM	DNA probes
ETEC	LT, ST	Traveler's diarrhea	O6:NM O6:H16 O8:H9 O25:NM O27:NM O63:H12	Immunoassays for LT or ST
Enteroadherent <i>E. coli</i>				
EAEC	AAF Afa/Dr adhesions, AIDA-1, EAST, PET	Persistent pediatric diarrhea	O44:H18	
DAEC ^a	Afa/Dr adhesions	Pediatric diarrhea, UTIs		HeLa cell adherence assay, DNA probes
Extraintestinal pathogens				
	Capsule	Septicemia and meningitis	K1	

^aDAEC causes both UTIs and gastrointestinal infections.

AAF, Aggregative adherence fimbriae; Afa/Dr, afimbrial adhesins; AIDA-1, adhesin involved in diffuse adherence; DAEC, diffusely adherent *E. coli*; EAEC, enteroaggregative *E. coli*; EHEC, enterohemorrhagic *E. coli*; EIEC, enteroinvasive *E. coli*; EPEC, enteropathogenic *E. coli*; EAST, enteroaggregative heat stable enterotoxin; ETEC, enterotoxigenic *E. coli*; HUS, hemolytic uremic syndrome; LT, labile toxin; MUG, 4-methylumbelliferyl β-D-glucuronide; NM, nonmotile; PET, plasmid-encoded toxin; SMAC, MacConkey agar containing sorbitol; ST, stable toxin; UPEC, uropathogenic *E. coli*; UTI, urinary tract infection.

Mucosal penetration and invasion do not appear to be part of ETEC disease. ETEC infections must be differentiated from other diarrheal illnesses that can appear similar.

Diagnosis of ETEC infection is made primarily by the patient's travel history, characteristic symptoms, and the isolation of solely lactose-fermenting organisms on differential

media in stool cultures. Immunologic assays to detect the two toxins from culture supernatants are commercially available. Multiplex PCR performed on stool samples to detect different diarrheagenic strains of *E. coli* are also available. For ETEC, the targets are the plasmid-borne *eltA* and *eltB* genes, which code for the A and B subunits of LT, and the *est* gene, which codes for ST.

Enteropathogenic *Escherichia coli*

EPEC was the first diarrheagenic *E. coli* described. It was identified as a cause of infantile diarrhea in 1945, but it was not until the late 1960s and 1970s that certain O serogroups of EPEC were linked to these isolates. However, only certain H antigenic types within each O serogroup were connected to the intestinal infections, and O serogrouping could not differentiate these *E. coli* strains from strains of normal biota. In 1978, Levine and colleagues attempted to settle the dispute concerning the pathogenic role of EPEC by challenging volunteers with EPEC strains that lacked the toxins of ETEC and the invasiveness of EIEC. The study showed that these EPEC strains caused distinct diarrhea. Subsequent studies showed the adhesive property of EPEC strains, a characteristic not seen in ETEC or EIEC strains. The virulence of EPEC is defined as producing attaching and effacing lesions on the intestinal epithelium but inability to produce Shiga toxins and LT or ST enterotoxins.

Diarrheal outbreaks caused by EPEC have occurred in hospital nurseries and daycare centers, but cases in adults are rarely seen. The infective dose is high, typically 10^8 to 10^{10} viable cells. The illness is characterized by low-grade fever, malaise, and vomiting, with persistent watery diarrhea, typically in children younger than 2 years of age. The stool typically contains large amounts of mucus, but apparent blood is not present. Detection of diarrheal illness attributable to EPEC depends primarily on the suspicion of the physician. In cases of severe diarrhea in children younger than 1 year of age, infection with EPEC should be suspected. These strains have a characteristic pattern of adherence to human epithelial-2 (HEp-2) cell cultures. Serologic typing with pooled antisera may be performed to identify EPEC serotypes, but this is generally used for epidemiologic studies rather than for diagnostic purposes. Diagnosis by nucleic acid amplification tests (NAATs) is based on detection of the *bfpA* gene, which codes for type IV bundle-forming pilus.

Enteroinvasive *Escherichia coli*

EIEC infection is rare in the United States and seen less commonly in developing countries than ETEC or EPEC. EIEC differs greatly from EPEC and ETEC strains. Enteroinvasive strains genetically and phenotypically resemble *Shigella* spp. and, like *Shigella*, produce dysentery with direct penetration, invasion, and destruction of the intestinal mucosa. The diarrheal illness resembles that produced by *Shigella*, although it tends to be milder, which likely leads to underreporting. EIEC is less invasive than *Shigella* spp., and the infective dose is 1000 to 10,000 times greater for EIEC. Direct transmission of EIEC from person to person via the fecal-oral route has been reported. EIEC infections seem to occur in adults and children alike. The clinical infection is characterized by fever, severe abdominal cramps, malaise, and bloody diarrhea.

The organisms might be easily misidentified because of their similarity to shigellae. EIEC strains can be nonmotile and generally do not ferment lactose; cross-reaction between shigellae and EIEC O antigens has been reported. EIEC isolates can be mistaken for nonpathogenic *E. coli*. Although EIEC does not decarboxylate lysine, more than 80% of *E. coli* strains do decarboxylate lysine. Misidentification might be another reason for cases of diarrheal illness resulting from EIEC being underreported.

The enteroinvasiveness of EIEC must be demonstrated for definitive identification. The tests currently available to determine the invasive property of EIEC are not performed in most clinical microbiology laboratories. It is possible to detect invasiveness using monolayer HEp-2 cell cultures or with NAATs to detect invasion genes. These assays detect the *ipaH* gene, which codes for the invasion plasmid antigen H. However, both EIEC and *Shigella* spp. express this gene. These assays are used to screen stool samples, eliminating the need for other tests to identify EIEC.

Shiga toxin-producing *Escherichia coli*

STEC refers to *E. coli* strains that produce **Shiga toxin 1** (Stx1) and/or Shiga toxin 2 (Stx2). The toxins are so named because of their similarity to the Shiga toxin produced by *Shigella dysenteriae* type 1. Stx is also referred to as verotoxin because this cytotoxin produces damage to Vero cells (African green monkey kidney cells)—hence the term *verotoxin*. Stx1 and Stx2 are immunologically distinct, and the genes, *stx1* and *stx2*, are carried on a phage that has integrated into the bacterial chromosome. Stx follows the A/B model of bacterial toxins.

Shiga toxins preferentially affect endothelial cells of the GI tract and renal glomeruli. In 1982, the O157:H7 strain of *E. coli* was first recognized during an outbreak of hemorrhagic diarrhea and colitis. These isolates become what is referred to as enterohemorrhagic *E. coli* (EHEC). The EHEC strain serotype O157 has since been associated with hemorrhagic diarrhea, colitis, and hemolytic uremic syndrome (HUS). HUS is characterized by low platelet count, hemolytic anemia, and kidney failure. EHEC is a subset of STEC that causes HUS.

The classic illness caused by EHEC produces a watery diarrhea that progresses to bloody diarrhea with abdominal cramps and low-grade fever or an absence of fever. However, symptoms can be variable from mild to life-threatening HUS. Stool specimens contain no leukocytes, which distinguishes it from dysentery caused by *Shigella* spp. or EIEC infections. ETEC infection is potentially fatal, especially in young children and older adults in nursing homes. Processed meats such as undercooked ground beef (40% of outbreaks), unpasteurized dairy products and apple cider, bean sprouts, and spinach all have been implicated in the spread of infection. In 2019, consumption of contaminated romaine lettuce was linked to a 27-state outbreak involving at least 167 people. Of reported patients, 85 were hospitalized and 15 developed HUS; there were no deaths.

Stx1 and Stx2 have been linked to over 250 serotypes. However, STEC O157 accounts for up to 80% of STEC infections worldwide and has a hospitalization rate of 17% to 46%. The infective dose for STEC O157 infection is extremely low, 50 to 200 colony-forming units. This likely explains its high incidence. Any of the STEC serotypes can cause clinical syndromes like that produced by STEC O157. In the United States, 265,000 cases of STEC are reported annually, and about 36% are STEC O157. See [Table 19.4](#) for a list of non-O157 STEC isolated from patients with bloody diarrhea, hemorrhagic colitis, or HUS.

In the laboratory, STEC can be identified by one of three methods:

- Stool culture on selective and highly differential medium, with subsequent serotyping
- Detection of the Shiga toxin in stool filtrates

- Demonstration of a fourfold or greater increase in Shiga toxin–neutralizing antibody titer

Current guidelines recommend that all stool specimens submitted for routine testing of enteric pathogens also include culture and toxin detection to identify STEC.

Stool culture procedures for STEC should incorporate MAC agar containing sorbitol (SMAC) instead of lactose, or SMAC with cefixime and tellurite (SMAC-CT). However, some strains of STEC are sensitive to tellurite. *E. coli* O157 does not ferment sorbitol in 24 hours, a characteristic that differentiates it from most other *E. coli* strains. STEC O157 appears colorless on SMAC agar, whereas most other strains produce pink colonies from sorbitol fermentation. The use of this differential medium facilitates the primary screening of STEC O157. Although isolation of other non-sorbitol-fermenting organisms may occur in 15% of cultures, STEC O157 produces heavy growth when present. An emergent phenotype, the sorbitol-fermenting, nonmotile *E. coli* O157:NM (NM indicates nonmotile) has been seen in European outbreaks, so relying on sorbitol as a single test to identify O157 strains is unwise. The use of CHROMagar O157 (Becton Dickinson, Franklin Lakes, NJ) has increased the recovery of ETEC O157 from stool specimens and is recommended over nonselective media. This medium has a proprietary formulation resulting in STEC O157 strains producing mauve-colored colonies.

In addition to sorbitol fermentation, the commercially available 4-methylumbelliferyl- β -D-glucuronide (MUG) assay is a biochemical test used to screen isolates for *E. coli* O157:H7. *E. coli* O157:H7 rarely produces the enzyme β -glucuronidase, whereas 92% of other strains do produce it. If the enzyme is present, MUG is cleaved, and a fluorescent product is formed. Sorbitol-negative and MUG-negative colonies are subsequently subcultured for serotyping using *E. coli* O157:H7 antiserum.

Enzyme-linked immunosorbent assay (ELISA) or latex agglutination can be used to detect the O157 antigen on culture isolates. In the latex agglutination test, isolates must be tested with the negative control to detect nonspecific agglutination. The O157 somatic antigen, which is usually the target in the commercial assays, can present a problem with regard to specificity because other enteric bacteria produce false-positive results. It is also important to confirm biochemically the identification of MUG-negative or sorbitol-negative colonies as *E. coli* isolates.

Testing for flagella antigens might require subculturing the bacteria several times. When colonies are taken directly from the SMAC plate, the test for the H7 antigen may be initially negative. It is helpful to grow these isolates in motility media first to enhance flagella production and agglutination with the latex particles. Approximately 85% of *E. coli* O157 isolates from humans possess H7, whereas 12% are nonmotile.

After serotyping, isolates may be tested for the presence of Stx or *stx* genes. Reports have shown that all *E. coli* O157:H7 strains produce high levels of cytotoxins, and STEC strains may be detected using cell culture assays with Vero cells. Because other toxins present in diarrhea stools can produce similar cytopathic effects, this test must be verified with specific antitoxins to Stx1 and Stx2.

If no EHEC colonies are identified, it is recommended that a loopful of bacteria (sweep) taken from the least selective agar plate be tested for Shiga toxin by enzyme immunoassay

(EIA) or NAAT. If the sweep is positive for Shiga toxin, individual colonies should then be tested. If the sweep is negative for Shiga toxin, the specimen is reported negative for STEC.

Patients with hemorrhagic colitis shed the organisms for only brief periods; nevertheless, Shiga toxins may still be detected in the stool. Free Shiga toxin present in stool specimens can be directly detected by EIAs in samples that yield negative culture results. The use of broth enrichment can increase the sensitivity of EIA testing. A portion of the stool sample should be placed into an enrichment broth. Gram-negative (GN) broth is commonly used. The broth should be incubated overnight at 35°C, and an EIA can be used to detect Stx. Even if stools are screened for Stx and cultured for STEC, as recommended, underreporting of STEC likely occurs.

Molecular diagnostic tests such as the BD MAX Enteric Panel (Becton Dickinson), Prodesse ProGastro SSCS assay (Hologic, San Diego, CA), Biofire Filmarray GI Panel (bioMérieux, Durham, NC), and Shiga Toxin Direct Test (Great Basin Scientific, Salt Lake City, UT) offer increased sensitivity and faster turnaround times compared with culture and immunoassay for detecting STEC strains. Multiplex molecular panels detect the *stx1* and *stx2* genes.

Enterohemorrhagic *Escherichia coli*

EAEC cells stick to each other, cultured cell monolayers, plastic surfaces, and the surface of the intestinal mucosa. They adhere packed in an aggregative “stacked-brick” pattern on the cells and between the cells by means of fimbriae and can lead to biofilm formation. These organisms produce watery diarrhea, vomiting, dehydration, and occasionally abdominal pain, mostly in children. White blood cells and red blood cells are often absent from the stool. The symptoms often persist for at least 2 or more weeks.

EAEC may be an important cause of diarrhea in infants in the United States and other countries. It should also be considered a cause of diarrhea in patients with human immunodeficiency virus (HIV) infection. In some regions, despite a high infective dose (10^8 to 10^{10}), EAEC symptomatic cases exceed ETEC cases. In 2011, an outbreak in Europe caused by EHEC (O104:H4) that also had virulence related to EAEC resulted in more than 3400 total infections and about 850 cases of HUS with 32 HUS-related deaths. Most of the cases occurred in Germany, and trace-back studies indicated that fresh sprouts produced by a farm in Lower Saxony were responsible for the outbreak. At least two cases were reported in the United States in individuals who had recently traveled to Germany.

The stacked-brick growth pattern on monolayer cell cultures is suggestive of EAEC; however, DNA probes for virulence genes offer a definitive identification. Isolates containing the *aggR* gene, a transcription regulator residing on a plasmid that activates several genes, are called typical EAEC. This gene is the target for molecular identification. EAEC also contains several toxin-encoding genes, on plasmids and the chromosome, that can be found on other diarrheagenic *E. coli* strains.

Other *Escherichia* species

There are currently seven recognized species within the genus *Escherichia*. Apart from *E. coli*, two other species are occasionally associated with human disease. *Escherichia fergusonii* has

been isolated from urine, blood, wounds, feces, and the gallbladder. *Escherichia albertii* is associated with diarrheal disease. Some *E. albertii* isolates carry the *stx2f* gene, which codes for a Shiga-like toxin, and the *cdtB* gene, which codes for a toxin found in *Clostridioides difficile*. These isolates can cause a condition resembling HUS.

Klebsiella

The genera *Klebsiella* can be found in the intestinal tract of humans and other animals as normal microbiota, or are free-living in soil, water, and on plants. These microorganisms have been associated with various opportunistic and health-care-associated infections, particularly pneumonia, wound infections, and UTIs. Members of these genera demonstrate variable biochemical reactions. Common characteristics include:

- Most grow on Simmons citrate and in potassium cyanide (KCN) broth.
- None produce H₂S.
- A few hydrolyze urea slowly.
- All are methyl red test negative and Voges-Proskauer positive.
- With a few exceptions, no indole is produced from tryptophan.
- Motility is variable.

The genus *Klebsiella* comprises several species, including *K. aerogenes*, *K. michiganensis*, *K. oxytoca*, *K. pneumoniae* subsp. *ozaenae*, *K. pneumoniae* subsp. *pneumoniae*, *K. pneumoniae* subsp. *rhinoscleromatis*, and *K. variicola*.

With the exception of *K. aerogenes*, the absence of motility distinguishes *Klebsiella* spp. from most other members of the family Enterobacteriaceae. Differential features of *Klebsiella* spp. are shown in Table 19.5. *K. pneumoniae* subsp. *pneumoniae* is the most commonly isolated and has the distinct feature of possessing a large polysaccharide capsule. The capsule offers the organism protection against phagocytosis and antimicrobial absorption, contributing to its virulence. The capsule is also responsible for the moist, mucoid colonies characteristic of *K. pneumoniae*. Occasionally evident in direct smears from clinical materials, this capsule is sometimes helpful in providing a presumptive identification. Fig. 19.2 illustrates the mucoid appearance of *K. pneumoniae* on MAC agar.

Colonization of gram-negative bacilli in the respiratory tracts of hospitalized patients, particularly by *K. pneumoniae* subsp. *pneumoniae*, increases with the length of hospital stay. *K. pneumoniae* subsp. *pneumoniae* is a frequent cause of lower respiratory tract infections among hospitalized patients and in immunocompromised hosts such as newborns, older adult patients, and seriously ill patients on respirators. Carbapenemase-producing *K. pneumoniae* is an important cause of ventilator-associated pneumonia. Patients with rectal and tracheal colonization of carbapenemase-producing *K. pneumoniae* receiving prolonged antimicrobial therapy for non-carbapenemase-producing *K. pneumoniae* infection are at increased risk for infection.

Other infections commonly associated with *K. pneumoniae* subsp. *pneumoniae* involving immunocompromised hosts are wound infections, UTIs, liver abscesses, and bacteremia. Reports describe hospital-acquired outbreaks of *Klebsiella* resistant to multiple antimicrobial agents in newborn nurseries. These outbreaks have been attributed to the plasmid transfer

Fig. 19.2 Mucoid appearance of *Klebsiella pneumoniae* on MacConkey agar.

of antimicrobial resistance. Although antimicrobial resistance has been increasing within the family Enterobacteriaceae, it is probably most severe with *K. pneumoniae* because of the presence of the *K. pneumoniae* carbapenemase.

Other *Klebsiella* spp. have been associated with numerous infections. *K. pneumoniae* subsp. *ozaenae* produces infections resembling those caused by *K. pneumoniae* subsp. *pneumoniae*. In addition, isolates have been linked to antimicrobial-associated hemorrhagic colitis. *K. pneumoniae* subsp. *ozaenae* has been isolated from nasal secretions and cerebral abscesses. This organism causes atrophic rhinitis, a tissue-destructive disease restricted to the nose. Biochemically, *K. pneumoniae* subsp. *ozaenae* is identical to *K. pneumoniae* subsp. *pneumoniae* except for its production of indole, and there are reports of ornithine-positive isolates as well. *K. pneumoniae* subsp. *ozaenae* is highly associated with the presence of plasmid-mediated ESBLs, contributing to the large numbers of antimicrobial-resistant hospital-acquired infections seen today.

K. pneumoniae subsp. *rhinoscleromatis* has been isolated from patients with rhinoscleroma, an infection of the nasal cavity that manifests as an intense swelling and malformation of the entire face and neck. Cases of rhinoscleroma have been reported in Africa and South America. This subspecies is not isolated from the environment or GI tract and is more commonly seen in tropical regions. Although it is relatively easy to differentiate among the *K. pneumoniae* subspecies with biochemical testing, MALDI-TOF mass spectrometry might not be able to do so.

K. aerogenes (formerly *Enterobacter aerogenes*) has been known to cause healthcare-associated infections such as respiratory infections, UTIs, sepsis, and post-neurosurgical meningitis, particularly in severely ill patients in intensive care units. *K. aerogenes* has also been linked to poor clinical outcomes in patients with bloodstream infections relative to those caused by *Enterobacter* spp. In recent years, *K. aerogenes* has become a significant multidrug-resistant pathogen. In particular, carbapenem-resistant *K. aerogenes* has been reported in several countries. Although colistin has been considered as a valuable therapeutic option, many reports of colistin-resistant *K. aerogenes* have been described during the past several years. The first identified plasmid-mediated colistin-resistant gene is the *mcr-1* gene, characterized as one of the main mechanisms of colistin resistance in *K. aerogenes*.

Phylogenetic studies resulted in the reclassification of some *Klebsiella* species into the genus *Raoultella*. These species, *Raoultella ornithinolytica* (indole and ornithine decarboxylase-positive), *Raoultella terrigena*, and *Raoultella planticola*, have been isolated rarely from the urine, respiratory tracts, and blood of humans.

Case check 19.1

The Case in Point illustrates typical predisposing risk factors for increased colonization of gram-negative bacilli in hospitalized patients. These include length of hospital stay, weakened immune response of older adult patients, and underlying serious illnesses, such as diabetes.

Enterobacter and Cronobacter

The genus *Enterobacter* is composed of at least 22 species. Many are found in the environment including soil, water, sewage, and vegetables. The *E. cloacae* complex consists of several (about a dozen) genetically similar, clinically relevant species that include *E. asburiae*, *E. cancerogenus*, *E. cloacae*, *E. ludwigii*, and *E. hormaechei*. These common healthcare-associated pathogens are of particular concern because of their increasing multidrug resistance. After *K. pneumoniae*, the *Enterobacter* spp. are the second most common carbapenem-resistant Enterobacteriaceae in the United States. *E. cloacae* and *E. hormaechei* are the two most common clinical isolates from this group and have been associated with pneumonia, wounds, UTIs, septicemia, and meningitis. Species have also been associated with contaminated medical devices.

Except for *E. asburiae*, members of this genus are motile. The colony morphology of many of the species resembles *Klebsiella* spp. when grown on MAC agar. *Enterobacter* spp. grow on Simmons citrate medium and in KCN broth; the methyl red test is negative, and the Voges-Proskauer test is positive. However, in contrast with *Klebsiella*, *Enterobacter* spp. usually produce ornithine decarboxylase; lysine decarboxylase is produced by most species but not by *E. asburiae* or *E. cloacae*. Distinguishing characteristics among *E. cloacae*, *E. hormaechei*, and *K. pneumoniae* are shown in Table 19.6. *E. asburiae* biochemically resembles *E. cloacae* and has been isolated from blood, urine, feces, sputum, and wounds. *E. cancerogenus* has been associated with osteomyelitis after traumatic wounds.

The genus *Cronobacter*, within the family Enterobacteriaceae, currently contains seven species. *C. sakazakii* and *C. malonaticus* are the most common human isolates. *C. sakazakii* has been documented as a pathogen in neonates causing meningitis, bacteremia, and necrotizing enterocolitis, often coming from powdered infant formula. It has also been isolated from cultures taken from brain abscesses and respiratory and wound infections. *C. sakazakii* typically produces a yellow pigment (Fig. 19.3). *C. malonaticus* is more often found in adults. Because of their biochemical similarities, it is difficult to identify cronobacters to the species level. The most accurate method is DNA sequencing of the *fusA* and *rpoB* genes.

Citrobacter

The genus *Citrobacter* consists of at least 19 species. The citrobacters are considered inhabitants of the GI tract and are associated with healthcare-associated infections, most frequently UTIs. The species most often isolated are *C. freundii* complex (includes *C. freundii*, *C. braakii*, and *C. youngae*, among others) and *C. koseri*. Although it is a known extraintestinal pathogen, *C. freundii* can be isolated in diarrheal stool cultures. *C. freundii* has been associated with infectious diseases acquired in hospital settings, often in patients older than 65 years of age. UTIs, pneumonias, septicemia, and intraabdominal abscesses have been reported. In addition, *C. freundii* has been associated with endocarditis in intravenous drug abusers. One reported case of *C. freundii* endocarditis required aortic valve replacement when antimicrobial therapy failed.

Most *Citrobacter* spp. hydrolyze urea slowly and ferment lactose, producing colonies on MAC agar that resemble those of *E. coli*. Almost all species grow on Simmons citrate medium (hence the genus name) and give a positive methyl red test. Because most (80%) *C. freundii* produce H₂S and some strains (50%) fail to ferment lactose, the colony morphology of *C. freundii* on primary selective media can be mistaken for *Salmonella* when isolated from stool cultures. Because of the pathogenic potential, it is important to differentiate *C. freundii* from *Salmonella*. Differentiation can be accomplished by using a minimal number of biochemical tests, such as urea hydrolysis and lysine decarboxylase. Most (70%) *C. freundii* hydrolyze urea, but all fail to decarboxylate lysine, whereas *Salmonella* fails to hydrolyze urea, and most isolates decarboxylate lysine. Several species of *Citrobacter* are similar and difficult to differentiate biochemically; hence, they are reported as *C. freundii* complex.

C. koseri is a pathogen documented as the cause of nursery outbreaks of neonatal meningitis, pneumonia, and brain abscesses. *C. braakii* is a rare human pathogen associated with community-acquired infections including septicemia in a patient with cervical cancer. Because of the difficulty in biochemically separating this species from other *Citrobacter* spp., infections might be underreported. *C. amalonaticus* is frequently found in feces, but no evidence has been found that it is a causative agent of diarrhea. It has been isolated from sites of extraintestinal infections, such as blood and wounds. *C. gillenii* and *C. murliniae* have also been isolated from human specimens.

Case check 19.2

The organism described in the Case in Point showed morphologic and biochemical characteristics of *Citrobacter* spp. The utilization of citrate is a key feature observed in this genus. *Citrobacter koseri* is frequently isolated from older adult males and is associated with antimicrobial resistance.
